LIST OF FIGURES
A remarkable connection has been established for antiferromagnetic 2-spin systems, including the Ising and hard-core models, showing that the computational complexity of approximating the partition function for graphs with maximum degree $\Delta$ undergoes a phase transition that coincides with the statistical physics uniqueness/non-uniqueness phase transition on the infinite $\Delta$-regular tree. Despite this clear picture for 2-spin systems, there is little known for multi-spin systems. We present the first analog of the above inapproximability results for multi-spin systems.

The main difficulty in previous inapproximability results was analyzing the behavior of the model on random $\Delta$-regular bipartite graphs, which served as the gadget in the reduction. To this end one needs to understand the moments of the partition function. Our key contribution is connecting: (i) induced matrix norms, (ii) maxima of the expectation of the partition function, and (iii) attractive fixed points of the associated tree recursions (belief propagation). We thus obtain a generic analysis of the Gibbs distribution of any multi-spin system on random regular bipartite graphs. We also treat in depth the $k$-colorings and the $q$-state antiferromagnetic Potts models.

Based on these findings, we prove that for $\Delta$ constant and even $k < \Delta$, it is NP-hard to approximate within an exponential factor the number of $k$-colorings on triangle-free $\Delta$-regular graphs. We also prove an analogous statement for the antiferromagnetic Potts model. Our hardness results for these models complement the conjectured regime where they are believed to have efficient approximation schemes. We systematize the approach to obtain a general theorem for the computational hardness of counting in antiferromagnetic spin systems, which we ultimately use to obtain the inapproximability results for $k$-colorings, $q$-state antiferromagnetic Potts model and antiferromagnetic 2-spin systems. The criterion captures in an appropriate way the statistical physics uniqueness phase transition on the tree.
CHAPTER I

INTRODUCTION

Over the last two decades, the increasing need to efficiently simulate large-scale random systems has led to an extensive development of approximate sampling techniques. This line of research is concretely captured in the framework of probabilistic graphical models, whose applications range in statistical machine learning, bioinformatics and computer vision, to name a few. As a byproduct of the intensive study of graphical models, the classical Markov Chain Monte Carlo approach for approximate sampling has been complemented by elaborate variational methods (see for example [51]). Rapid as the development of approximate sampling techniques might be, the computational limits of these methods and the reasons behind their practical success (or failure) remain for the large part elusive.

Recently, a remarkable connection has been established for spin systems, a natural class of graphical models, relating directly the complexity of approximate sampling/counting in computer science and the theory of phase transitions in statistical physics. A crucial part in this connection is in establishing phase transitions for spin systems on random graphs. This thesis is devoted to developing further these ideas and understanding the boundaries of efficient computation.

1.1 Spin Systems

Spin systems are a general framework that captures well-studied models from statistical physics, such as the Ising and Potts models, and also models of particular combinatorial interest, such as $k$-colorings and the hard-core lattice gas model defined on independent sets. We next give a general definition of spin systems and review later the most interesting models.
1.1.1 General Definition

For an integer \( q \geq 2 \), a \( q \)-spin system is specified by a symmetric \( q \times q \) interaction matrix \( B = (B_{ij})_{i,j \in [q]} \) with non-negative entries, which specify the strength of the interaction between the spins. For example, the interaction matrix for the Potts model with parameter \( B \geq 0 \) has off-diagonal entries equal to 1 and its diagonal entries equal to \( B \).

For a finite undirected graph \( G = (V,E) \), a \( q \)-spin system is a probability distribution \( \mu_G \) over the space \( \Omega_G \) of all configurations, i.e., spin assignments \( \sigma : V \rightarrow [q] \). The weight of a configuration \( \sigma \in \Omega_G \) is the product of neighboring spin interactions, that is,

\[
w_G(\sigma) = \prod_{(u,v) \in E} B_{\sigma(u)\sigma(v)}.
\]  

(1)

The spin system has hard constraints if there exist \( i,j \in [q] \) such that \( B_{ij} = 0 \). Note that in the presence of hard constraints, every configuration with positive weight does not have the spins \( i,j \) assigned to adjacent vertices. A permissive spin system is a system for which there exists a spin \( i \) such that \( \min_j B_{ij} > 0 \). Thus, in a permissive spin system every partial assignment has an extension to an assignment of \( V \). Obviously, permissiveness can be an issue only if the system has hard constraints.

The partition function of the spin system is the aggregate weight of the configurations, i.e.,

\[
Z_G = \sum_{\sigma \in \Omega_G} w_G(\sigma).
\]  

(2)

The Gibbs distribution \( \mu_G \) is defined as \( \mu_G(\sigma) = w_G(\sigma)/Z_G \). In statistical physics, the Gibbs distribution specifies an equilibrium state of the system. We will drop the the subscript \( G \) whenever the graph under consideration is clear from context.

Often, the edge interaction is supplemented by a set of external fields which bias the frequency of one or more spins. More precisely, a set of external fields is specified by a \( q \)-dimensional vector \( \lambda = (\lambda_i)_{i \in [q]} \) with non-negative entries. The weight function (1) is given then by

\[
w_G(\sigma) = \prod_{u \in V} \lambda_{\sigma(u)} \prod_{(u,v) \in E} B_{\sigma(u)\sigma(v)}.
\]
Note that setting all the $\lambda_i$'s equal to 1 yields the weight function (1), the so called no external field case.

**Remark 1.** In the largest portion of this thesis, we will work with $\Delta$-regular graphs. For this class of graphs, there is a generic way to restrict our attention to spin systems with no external fields. In particular, the spin system specified by $B, \lambda$ is equivalent to a spin system with interaction matrix $B_\lambda$ where the $ij$-entry of $B_\lambda$ is given by $\lambda_i^{1/\Delta} \lambda_j^{1/\Delta} B_{ij}$.

For completeness, we next review some well-known models with significant combinatorial or statistical physics interest. The experienced reader should skip the following two subsections.

**1.1.2 2-spin Systems**

The hard-core and Ising models are the most interesting models of 2-spin systems. It will be useful however to give the more general context of 2-spin systems.

A 2-spin system is specified by parameters $B_1, B_2 \geq 0$ and $\lambda > 0$. The parameters $B_1, B_2$ specify the edge interaction, while $\lambda$ is the external field on the spin 1. To avoid trivial models we will invariably assume that at least one of $B_1, B_2$ is bigger than 0. The edge interaction matrix for a 2-spin system with parameters $B_1, B_2$ is given by

$$B = \begin{bmatrix} B_1 & 1 \\ 1 & B_2 \end{bmatrix}.$$  

The system is antiferromagnetic if $B_1 B_2 < 1$ and ferromagnetic if $B_1 B_2 > 1$. The classification captures whether neighboring spins are favored to be the same. This notion will make much more sense in the following special cases of 2-spin systems.

The two most interesting models of 2-spin systems are the hard-core and Ising models. The hard-core model is an idealized lattice gas model in statistical physics and has as a parameter only the external field $\lambda$, also known as the fugacity or activity of the gas. It corresponds to the special case where $B_1 = 1, B_2 = 0$ (in particular, it is an antiferromagnetic 2-spin system). In the standard formulation of the hard-core model, the spins take 0,1 values and vertices which are assigned spin 1 are called occupied, and unoccupied otherwise.
The external field $\lambda$ acts on the vertices assigned spin 1. It is straightforward to verify that the Gibbs distribution is supported on configurations which induce an independent set (by looking at the vertices assigned the spin 1). Recall, an independent set is a set of vertices which are mutually non-adjacent. The partition function may be alternatively written as

$$Z_G = \sum_I \lambda^{|I|},$$

where the sum ranges over all independent sets of $G$. Note that for $\lambda = 1$, the partition function is the total number of independent sets and the Gibbs distribution is the uniform distribution over the independent sets.

The Ising model was introduced as a model of ferromagnetism by Lenz, which was studied in Ising’s PhD thesis [24]. In the 2-spin setting given above, it corresponds to the particular case $B_1 = B_2 = B$. In the no external field case, the Gibbs distribution of the Ising model can be viewed as a weighted probability distribution on the set of cuts of the graph $G$. The model is antiferromagnetic when $B < 1$ and ferromagnetic otherwise. Note that when $B < 1$, cuts with larger size are favored, in contrast to the case $B > 1$ where the largest weight configurations are trivially the assignments in which every vertex has the same spin. In the standard formulation of the ferromagnetic Ising model with no external field, the spins take $\pm 1$ values and the Gibbs distribution is given by

$$\mu_G(\sigma) \propto \exp \left( \beta \sum_{(u,v) \in E} \sigma(u)\sigma(v) \right), \quad (3)$$

where $\beta \geq 0$ corresponds to what is known as the inverse temperature. In our setting, $B = \exp(\beta)$. The antiferromagnetic regime is obtained by replacing $\beta$ with $-\beta$ (and keeping $\beta \geq 0$).

To conclude our review of 2-spin systems, we note that there is no generality to be gained by having extra parameters in the formulation of a 2-spin system, provided that the presence of an external field is allowed.

1.1.3 The $k$-colorings and the $q$-state Potts models

We next look at models with more than 2-spins. The most important such example is the $k$-colorings model, where $k \geq 3$ is the number of colors/spins. Later in this thesis, we will
use $q$ instead of $k$ to have a uniform account of spin systems. Recall that a proper $k$-coloring of a graph $G$ is an assignment of $k$ colors to the vertices of $G$ such that no two adjacent vertices have the same color.

The Gibbs distribution of a graph $G$ in the $k$-colorings model is the uniform distribution over the set of proper $k$-colorings of the graph $G$ with $k$-colors. In particular, the partition function is the total number of proper $k$-colorings. In contrast to 2-spin systems, note that the Gibbs distribution is not always well-defined if the graph $G$ does not admit a proper $k$-coloring. This is clearly not an issue when $k$ is greater or equal than the chromatic number $\chi(G)$, however getting a handle on the latter is in general an NP-hard problem. For graphs of maximum degree $\Delta$, the well known Brook’s theorem asserts that $\chi(G) \leq \Delta$ unless the graph is complete or an odd cycle. Much better (algorithmic) bounds on the chromatic number are known, and the situation becomes better if we impose further restrictions (such as girth) to the graph $G$. We will return to this point later.

The $q$-state Potts model is a generalization of the $k$-colorings model. Precisely, the model has $q$ spins and a parameter $B > 0$ (the temperature). The weight of a configuration $\sigma$ is $B^{m(\sigma)}$, where $m(\sigma)$ is the number of monochromatic edges under the configuration $\sigma$, that is, edges $(u,v)$ with $\sigma(u) = \sigma(v)$. The model is antiferromagnetic when $B < 1$ and antiferromagnetic otherwise. Note that the case $B = 0$ corresponds to the $k$-colorings model. The edge interaction matrix of the $q$-state Potts model has off-diagonal entries equal to 1, and on the diagonal equal to $B$. Note that the Ising model is the particular case of the Potts model with $q = 2$.

1.2 Phase Transitions in Spin Systems

From the viewpoint of statistical physics, a phase transition is an abrupt change in the macroscopic properties of a system due to small changes in the microscopic parameters of the system. A well known example of a phase transition is the transformation of the states of matter (solid, liquid, gas). To better align however with the mathematical development of phase transitions, it will be useful to describe the phase transition of the Ising model on the two dimensional integer lattice $\mathbb{Z}^2$ (which we will abbreviate in short as 2D Ising). We
will work in the standard notation of the Ising model, given in (3).

To motivate the discussion, let us first observe that the Gibbs distribution is well-defined only for finite graphs. In statistical physics however, systems have typically a large number of components, effectively infinite. This raises the question of how to describe the equilibrium states in an infinite system as an extension of the (finite) Gibbs distribution. Ideally, the description of such an equilibrium would capture that finite subsystems are in equilibrium with the rest of the system. Let us formalize the last sentence.

Consider the 2D Ising model on $\mathbb{Z}^2$. Let $\Lambda_n$ be a square box around the origin of $\mathbb{Z}^2$ with length $\lfloor \sqrt{n} \rfloor$. The set of vertices in $\mathbb{Z}^2 \setminus \Lambda_n$ which have neighbors in $\Lambda_n$ will be called the (external) boundary of $\Lambda_n$ and denoted as $\partial \Lambda_n$. We will consider configurations which assign the same spin to the boundary vertices. Specifically, the $(+)$-boundary condition will refer to the set of configurations $\sigma : \Lambda_n \cup \partial \Lambda_n \to \{\pm 1\}$ where all vertices in $\partial \Lambda_n$ are assigned spin $+1$. Define analogously the ($-$)-boundary condition. Next, we will examine whether the boundary condition affects the marginal probability that the origin is assigned the spin $+1$. To do this, denote the origin by $\rho$ and the Gibbs distribution on $\Lambda_n \cup \partial \Lambda_n$ by $\mu_n := \mu_{\Lambda_n \cup \partial \Lambda_n}$. Let

$$p_n^+ := \mu_n(\sigma(\rho) = +1 | \forall u \in \partial \Lambda_n, \sigma(u) = +1),$$

$$p_n^- := \mu_n(\sigma(\rho) = +1 | \forall u \in \partial \Lambda_n, \sigma(u) = -1).$$

Given that the model is ferromagnetic, it is reasonable to expect that $p_n^+ > p_n^-$. The phase transition in $\mathbb{Z}^2$ is captured by whether the bias persists in the limit $n \to \infty$. More precisely, if

$$p_n^+ - p_n^- \to 0,$$

the model is in the \textit{uniqueness regime} of $\mathbb{Z}^2$, and otherwise in the \textit{non-uniqueness regime}. To justify this terminology, (4) captures whether there are multiple equilibrium states of the infinite system. In particular, whenever (4) holds, it can be proved that finite subregions which are far away are asymptotically independent and hence the system is at equilibrium. It is reasonable to expect that this would hold when the edge interaction is weak, i.e., when $\beta$ is small. On the other hand, if $\beta$ is large, then (4) fails and the system is characterized
by long range correlations, signifying the existence of multiple equilibrium states. In fact, the transition from the uniqueness regime and the non-uniqueness regime is sharp: Onsager \cite{44} solved the model and proved the existence of a critical temperature $\beta_c(\mathbb{Z}^2)$ such that whenever $\beta > \beta_c(\mathbb{Z}^2)$ the model is in the non-uniqueness regime, and in uniqueness otherwise.

To summarize, the phase transition on $\mathbb{Z}^2$ captures the existence of long range correlations in the large scale limit; whenever the correlations persist, the system has multiple equilibrium states. So far, we have been intentionally obscure on the definition of the equilibrium states in infinite systems, since the mathematical formulation is more strenuous. An equilibrium state in $\mathbb{Z}^2$ is a probability distribution on the space of all configurations, known as an \textit{infinite volume Gibbs measure}. Roughly, an infinite volume Gibbs measure is consistent with all Gibbs distributions on finite subgraphs and all boundary conditions on them. This should bear some resemblance with the argument above; a formal definition and further discussion is given in Section 1.2.1.

We conclude this part by noting that there are other ways to view the phase transition on $\mathbb{Z}^2$, the classical statistical physics view concentrates on singularities of the limit of the logarithm of the partition function or discontinuities of macroscopic properties of the system.

\subsection{1.2.1 Infinite Volume Gibbs Measures}

Dobrushin \cite{13} and Lanford and Ruelle \cite{31} formulated the concept of an infinite volume Gibbs measure. This is a natural extension of the Gibbs distribution in the setting of infinite graphs and can be therefore interpreted as an equilibrium state of an infinite system. In the previous section, we described the motivation behind the definition of an infinite volume Gibbs measure. In this section, we shall give a formal definition for a $q$-spin system with interaction matrix $B$. For a more elaborate treatment, the reader should refer to \cite{19}.

Let $G = (V, E)$ be a graph, where $V$ is a countable set of vertices. For convenience, we will assume that the graph is locally finite, i.e., every vertex has bounded degree. A configuration $\sigma : V \to [q]$ will be called feasible if for every edge $(u, v) \in E$, it holds that
For a configuration $\sigma$ and a subset $S \subseteq V$, the restriction of $\sigma$ to $S$ will be denoted by $\sigma_S$.

Let $\Lambda$ be a finite subgraph of $G$ and denote by $\partial \Lambda$ its external boundary, i.e., the set of vertices which do not belong in $\Lambda$ but are adjacent to a vertex in $\Lambda$. With a minor abuse of notation, for a configuration $\sigma$, we will denote by $\sigma_\Lambda$ the restriction of $\sigma$ to the set of vertices in $\Lambda$. We will denote by $\mu_{\Lambda \cup \partial \Lambda}$ the finite volume Gibbs distribution on $\Lambda \cup \partial \Lambda$.

A Gibbs measure $\nu$ is defined by requiring $\nu$ to agree with the finite Gibbs distribution inside every finite region $\Lambda$, given that the configuration outside $\Lambda$ is kept fixed. More precisely, we have the following definition.

**Definition 1.** Let $B$ be the interaction matrix of a $q$-spin system and $G = (V,E)$ be a locally finite graph. A probability measure $\nu$ over the space of all feasible configurations on $G$ is a Gibbs measure for the spin model defined by $B$, if for every finite region $\Lambda \subseteq G$, and $\nu$-almost every feasible configuration $\eta$, it holds that

$$
\nu(\sigma_\Lambda = \tau | \sigma_{G \setminus \Lambda} = \eta_{G \setminus \Lambda}) = \mu_{\Lambda \cup \partial \Lambda}(\sigma_\Lambda = \tau | \sigma_{\partial \Lambda} = \eta_{\partial \Lambda}),
$$

for every $\tau : \Lambda \to [q]$.

With the definition of an infinite volume Gibbs measure in place, we are now ready to give a formal definition of uniqueness/non-uniqueness. The definition captures the existence of multiple equilibrium states for the infinite system.

**Definition 2.** Let $B$ be the interaction matrix of a $q$-spin system and $G = (V,E)$ be a locally finite graph. The $q$-spin system is in the uniqueness regime of $G$ if there exists a unique infinite volume Gibbs measure. Otherwise, the $q$-spin system is in the non-uniqueness regime of $G$.

To relate with the definition of the uniqueness regime in the 2D Ising model, we give the following equivalent definition of uniqueness, whose proof can be found in e.g. [19].

**Lemma 1.** Let $B$ be the interaction matrix of a $q$-spin system and $G = (V,E)$ be a locally finite graph. The $q$-spin system is in the uniqueness regime of $G$ iff for every finite subgraph
\( \Lambda \subseteq G \), there exists a sequence of finite regions \( \Lambda \subseteq \Lambda_1 \subseteq \Lambda_2 \subseteq \cdots \subseteq \Lambda_n \subseteq \ldots \) with \( \bigcup_n \Lambda_n = V \) such that for every pair of feasible configurations \( \eta, \eta' \) on \( G \), it holds that

\[
\left| \mu_{\Lambda_n \cup \partial \Lambda_n} (\sigma_{\Lambda} = \tau \mid \sigma_{G \setminus \Lambda_n} = \eta_{G \setminus \Lambda_n}) - \mu_{\Lambda_n \cup \partial \Lambda_n} (\sigma_{\Lambda} = \tau \mid \sigma_{G \setminus \Lambda_n} = \eta'_{G \setminus \Lambda_n}) \right| \to 0
\]

for all \( \tau : \Lambda \to [q] \).

Equation (4) for the 2D Ising model captures the condition in Lemma 1, in the case that \( \Lambda \) is the origin of \( \mathbb{Z}^2 \) and \( \eta, \eta' \) are the configurations on \( \mathbb{Z}^2 \) where all vertices are assigned \( +1, -1 \), respectively. That for the ferromagnetic Ising model it suffices to look only at these two extreme configurations follows from a correlation inequality known as Griffith’s inequality.

1.2.2 A Primer on the Uniqueness Threshold of the Infinite Tree

Let \( \Delta \geq 3 \). The infinite \( \Delta \)-regular tree, denoted by \( T_\Delta \), is known in statistical physics as the Bethe lattice with coordination number \( \Delta \).

The uniqueness threshold on \( T_\Delta \) will be crucial for our arguments. \( T_\Delta \) has been conjectured to be the worst case graph of maximum degree \( \Delta \) for long range correlations. The reason being that the influence from boundary conditions should be maximized when the number of vertices in the boundary is maximized. In this sense, \( T_\Delta \) has the most vertices at distance \( \ell \) from the root. While the conjecture has been proved to be wrong in general [48], for natural spin systems such as \( k \)-colorings or the antiferromagnetic Potts model it is believed to be true. In fact, for 2-spin systems the conjecture has been shown to be true by [52] in the context of the hard-core model and was later extended in [47, 32] for antiferromagnetic 2-spin systems. Later, the reader will find that our inapproximability results hinge upon the long-range correlation on the tree.

Determining the uniqueness threshold on \( T_\Delta \) is generally simpler than on other graphs, due to its acyclic structure. However, technical difficulties are not absent; for example, it is surprising to some extent that the uniqueness threshold for the antiferromagnetic Potts model is not known, despite that it is conjectured to have the particularly simple form

\[
B_c(\Delta) = \frac{\Delta - q}{\Delta}.
\]
We next give a flavor of the arguments that come into play when determining the uniqueness threshold on the tree, to help motivating the upcoming sections. We do this in the simplest possible case, the hard-core model with activity $\lambda$. Note, the uniqueness threshold for the hard-core model has been found by Kelly [30] to be

$$
\lambda_c(T_\Delta) = \frac{(\Delta - 1)^{\Delta-1}}{(\Delta - 2)^\Delta},
$$

so we will focus on those parts that will be most important for us.

Following the same approach as in the 2D Ising model, we examine the Gibbs distribution for the hard-core model on finite trees of depth $n$. It will be more convenient to look at complete $(\Delta - 1)$-ary trees of depth $n$, where the root has degree $\Delta - 1$ (this is to avoid accounting for the root separately, otherwise nothing really changes). We denote the depth $n$ tree with $T_n$ and its set of leaves by $S_n$. We will examine two extreme boundary configurations on the leaves which, due to certain monotonies of the hard-core model, turn out to have the largest influence on the root: the $(+)$-boundary, where all the leaves are occupied, and the $(−)$-boundary, where all the leaves are unoccupied. Let $p_n^+, p_n^−$ be the marginal probabilities that the root of $T_n$ is occupied conditioned on the $(+), (−)$ boundary conditions respectively. Formally, if $\rho$ denotes the root of the tree and $\mu_n := \mu_{T_n}$ the Gibbs distribution on $T_n$, let

$$
p_n^+ := \mu_n(\sigma(\rho) = 1 \mid \forall u \in S_n, \sigma(u) = 1), \quad p_n^- := \mu_n(\sigma(\rho) = 1 \mid \forall u \in S_n, \sigma(u) = 0).
$$

The hard-core model with activity $\lambda$ is then in the uniqueness regime of $T_\Delta$ if $p_n^+ - p_n^- \to 0$ as $n \to \infty$. We note here that, in contrast to the Ising model, it does not hold that $p_n^+ > p_n^−$ for all $n$; instead, it holds that

$$
p_{2n}^+ > p_{2n}^− \quad \text{and} \quad p_{2n+1}^+ < p_{2n+1}^−. \quad (5)
$$

This is a consequence of the fact that the hard-core model is an antiferromagnetic 2-spin system. Unlike to the case of $\mathbb{Z}^2$, we can get easily a handle on $p_n^+, p_n^−$ by writing tree recursions. One thus obtains the following recursions

$$
p_{n+1}^+ = f(p_n^+), \quad p_{n+1}^- = f(p_n^-), \quad \text{where} \quad f(x) := 1 - \frac{1}{1 + \lambda(1 - x)^{\Delta-1}}. \quad (6)
$$
The initial conditions for the recursions are given by \( p_0^+ = 1 \) and \( p_0^- = 0 \). It can easily be checked that the fixpoint equation \( x = f(x) \) has a unique solution \( x_o \) for all values of \( \lambda \). When \( \lambda \leq \lambda_c(T_\Delta) \), the fixpoint \( x_o \) is stable and both \( p_n^+ \) and \( p_n^- \) converge to \( x_o \). However, when \( \lambda > \lambda_c(T_\Delta) \), the fixpoint \( x_o \) is unstable, i.e., it holds that \( f'(x_o) < -1 \). This implies that the sequences \( p_n^+ \) and \( p_n^- \) do not converge: otherwise, their limit would have to be equal to \( x_o \), but close to \( x_o \) the recursion oscillates.

To better understand what is happening in the regime \( \lambda > \lambda_c(T_\Delta) \), (5) suggests looking at the recursion (6) for two steps, i.e.,

\[
p_{2n+2}^+ = g(p_{2n}^+), \quad p_{2n+2}^- = g(p_{2n}^-), \quad \text{where } g(x) := f(f(x)),
\]

and \( p_0^+ = 1 \) and \( p_0^- = 0 \). The fixpoint equation \( x = g(x) \) has now three fixpoints \( x^+ > x_o > x^- \) in the regime \( \lambda > \lambda_c(T_\Delta) \). The unstable fixpoint \( x_o \) of \( f \) remains unstable for \( g \) as well, i.e., \( g'(x_o) > 1 \). The remaining two fixpoints \( x^+, x^- \) satisfy \( |g'(x)| < 1 \) and are hence stable. Combining the above observations, one can easily see that \( p_{2n}^+ \downarrow x^+ \) and \( p_{2n}^- \uparrow x^- \).

This suggests the existence of (at least) two different infinite volume Gibbs measures in the regime \( \lambda > \lambda_c(T_\Delta) \). The first is obtained by fixing the leaves on \( T_{2n} \) to be occupied and taking the weak limit as \( n \to \infty \); the marginal probability of the root being occupied is \( x^+ \) in the limiting measure. The second is obtained by fixing the leaves on \( T_{2n} \) to be unoccupied and taking again the weak limit as \( n \to \infty \); in this case, the marginal probability of the root being occupied is \( x^- \) in the limiting measure. A more explicit construction of these two infinite volume Gibbs measures is given in Section 1.2.3.1.

We now summarize our observations. First, we saw that one can get a handle on the uniqueness threshold on the tree by looking at appropriate tree recursions. In the case of the hard-core model, due to the (anti)monotonicity properties that the model exhibits, we had to go up to depth two only, and look at the two extreme boundary conditions (in general this need not be the case). Second, the asymptotic stability of the fixpoints provided us with useful information on the location of the phase transition and helped us to identify infinite volume Gibbs measures.

In the next section, we will see how to generalize in an appropriate way these observations.
to a general $q$-spin system.

1.2.3 Translation Invariant Gibbs measures on the Bethe Lattice

In general, infinite volume Gibbs measures can be extremely complex and particularly hard to define. However, on lattice graphs, it is usually the case that a natural class of Gibbs measures can be identified which are invariant under a subgroup of the automorphism group of the graph. In this section, we will view two such general constructions on the infinite $\Delta$-regular tree. These constructions will naturally lead us to the notion of semi-translation invariant uniqueness, which is a weaker notion of uniqueness, albeit easier to formulate. Most importantly, this auxiliary uniqueness threshold will manifest itself in our later investigation of random $\Delta$-regular graphs, allowing us to connect the phase transition on the infinite $\Delta$-regular tree with properties of the Gibbs distribution in random graphs.

Recall from Section 1.2.2 that the Bethe lattice is an (infinite) regular tree. We will denote the infinite $\Delta$-regular tree by $T_\Delta$. To ease exposition, it will also be helpful to specify a root $\rho$ on $T_\Delta$. A translation invariant Gibbs measure on $T_\Delta$ is a measure $\nu$ on the space of configurations which is invariant under all automorphisms of $T_\Delta$. Among other things, this implies that under $\nu$, the marginal spin distribution of each vertex of the tree is identical, i.e., the distribution $\nu(\sigma(v) = \cdot)$ does not depend on the vertex $v$. As we shall display at the end of this section, translation invariant Gibbs measures correspond to fixpoints of the depth one tree recursions:

$$\hat{R}_i \propto \left( \sum_{j=1}^{q} B_{ij} R_j \right)^{\Delta - 1}.$$  \hspace{1cm} (7)

The fixpoints of the tree recursions (7) are those $r = (R_1, \ldots, R_q)$ such that:

$$\hat{R}_i \propto R_i \text{ for all } i \in [q].$$

Before proceeding, for the sake of a concrete example, we align the recursions (7) with the recursion (6) for the hard-core model. Recall that the interaction matrix of the hard-core model is given by $\begin{bmatrix} 1 & 1 \\ 1 & 0 \end{bmatrix}$. Hence, (7) takes the form:

$$\hat{R}_1 \propto (R_1 + R_2)^{\Delta - 1}, \quad \hat{R}_2 \propto \lambda R_1^{\Delta - 1}.$$
Note here the minor change to account for the presence of the external field, one can alternatively start from Remark 1 to derive the same recursion but this requires slightly more work. If we set \( \hat{p} = \frac{R_2}{R_1 + R_2} \) and \( p = \frac{R_2}{R_1 + R_2} \), we obtain \( \hat{p} = f(p) \), exactly as in (6).

As we saw in Section 1.2.2, for the hard-core model we needed to look at two steps of the tree recursions to get the correct limiting behavior, as a consequence of the fact that it is an antiferromagnetic spin system. It is natural thus to also examine the Gibbs measures arising from fixpoints after iterating two steps of the tree recursions.

We may define a semi-translation invariant Gibbs measure on \( \mathbb{T}_\Delta \) as a measure \( \nu \) which is invariant under parity-preserving automorphisms of \( \mathbb{T}_\Delta \); the marginal spin distribution of a vertex of the tree depends now on the parity of its distance from the root of the tree. Semi-translation invariant Gibbs measures correspond to fixpoints of the depth two tree recursions:

\[
\hat{R}_i \propto \left( \sum_{j=1}^{q} B_{ij} C_j \right)^{\Delta-1} \quad \text{and} \quad \hat{C}_j \propto \left( \sum_{i=1}^{q} B_{ij} R_i \right)^{\Delta-1}. \tag{8}
\]

The fixpoints of the tree recursions (8) are those \( r = (R_1, \ldots, R_q) \) and \( c = (C_1, \ldots, C_q) \) such that:

\[
\hat{R}_i \propto R_i \text{ for all } i \in [q], \quad \hat{C}_j \propto C_j \text{ for all } j \in [q].
\]

A fixpoint of (8) will be called translation invariant iff \( R_i \propto C_i \) for all \( i \in [q] \).

Following the observations in Section 1.2.2, it will be important to have the notion of stability for a fixpoint of the tree recursions. The following definition captures whether the tree recursions (7), (8) are stable under small perturbations around a fixpoint. The formal definition uses the Jacobian matrix of a vector valued function \( f : \mathbb{R}^n \to \mathbb{R}^n \). The Jacobian of \( f \) at a point \( \mathbf{x} \in \mathbb{R}^n \) is the \( n \times n \) matrix whose \( i,j \) entry is the partial derivative of the \( i \)-th component of \( f \) with respect to \( x_j \) (the \( j \)-th component of \( \mathbf{x} \)).

In this language, our observations in Section 1.2.2 translate as follows in the case of the hard-core model: in the non-uniqueness regime, the Jacobian of the depth one tree recursions at the unique fixpoint has spectral radius greater than one, while the Jacobian of the depth two tree recursions at each of the other two fixpoints has spectral radius less
than one. We capture this in a more general setting as follows.

**Definition 3.** A fixpoint $r = (R_1, \ldots, R_q)$ of the depth one tree recursions (7), viewed as a function $f : (R_1, \ldots, R_q) \mapsto (\hat{R}_1, \ldots, \hat{R}_q)$, is Jacobian attractive if the Jacobian of $f$ at $r$ has spectral radius less than 1.

Similarly, a fixpoint $r = (R_1, \ldots, R_q), c = (C_1, \ldots, C_q)$ of the depth two tree recursions (8), viewed as a function $f : (R_1, \ldots, R_q, C_1, \ldots, C_q) \mapsto (\hat{R}_1, \ldots, \hat{R}_q, \hat{C}_1, \ldots, \hat{C}_q)$, is Jacobian attractive if the Jacobian of $f$ at $(r, c)$ has spectral radius less than 1.

We next define the notion of semi-translation invariant uniqueness on $\mathbb{T}_\Delta$. This is a simpler notion of uniqueness, which captures whether there are multiple semi-translation invariant Gibbs measures. In turn, the latter corresponds to checking whether there are multiple fixpoints to the tree recursions (8).

**Definition 4.** A spin system with interaction matrix $B$ is in the semi-translation invariant uniqueness regime of $\mathbb{T}_\Delta$, if there is a unique fixpoint to the tree recursions (8). Otherwise, the model is in the semi-translation invariant non-uniqueness regime of $\mathbb{T}_\Delta$.

We now discuss the interplay between Definitions 3 and 4. It can be proved by a variational argument (described in Section 1.3) that a translation invariant fixpoint, i.e., a fixpoint of the recursions (7), always exists. In the uniqueness regime of $\mathbb{T}_\Delta$, the fixpoints of both the recursions (7) and (8) should correspond to the same infinite volume Gibbs measure. On the other hand, if there exists a fixpoint of either (7) or (8) which is not stable, then we will prove (see Theorem 2) that there must exist another fixpoint of (7) or (8), signifying that the spin system is in the non-uniqueness regime of $\mathbb{T}_\Delta$.

It should be noted at this point that a spin system may be in the semi-translation invariant uniqueness regime of $\mathbb{T}_\Delta$, but not in the uniqueness regime of $\mathbb{T}_\Delta$, a concrete example will be given shortly. However, for the most interesting models, the relevant thresholds are typically close if not identical. In particular, for 2-spin systems, the semi-translation invariant non-uniqueness threshold coincides with the uniqueness threshold. For the antiferromagnetic Potts model, the uniqueness threshold is conjectured to be $B_c(\mathbb{T}_\Delta) = \frac{\Delta - q}{\Delta}$ and we will prove that this is the semi-translation invariant non-uniqueness threshold.
for $k$-colorings there is a slight discrepancy: uniqueness holds when $k \geq \Delta + 1$, while semi-translation invariant non-uniqueness holds for $k \geq \Delta$.

1.2.3.1 Gibbs measures from Fixpoints of the Tree Recursions

Here, we will explicitly show that the tree recursions (7) and (8) correspond to translation and semi-translation invariant invariant Gibbs measures on $T_\Delta$. Note that this argument is well-known; we just give the construction for completeness.

Given a fixpoint of the depth one tree recursions (7), a Gibbs measure on $T_\Delta$ for the spin system specified by $B$, can be defined by a broadcasting process. Namely, for $r = (R_1, \ldots, R_q)$, define the probability vector $\alpha = (\alpha_1, \ldots, \alpha_q)$ given by

$$\alpha_i = \frac{R_i \sum_{j=1}^q B_{ij} R_j}{\sum_{i,j} B_{ij} R_i R_j},$$

and consider the $q \times q$ matrix $M = (M_{ij})_{i,j \in \{q\}}$ whose $(i,j)$-entry is given by $B_{ij} R_j / \sum_{j=1}^q B_{ij} R_j$.

It is immediate to verify that $M$ is stochastic, so we can view $M$ as a transition kernel. Moreover, by construction $\alpha M = \alpha$, so that $\alpha$ is the stationary distribution of the kernel $M$. With these observations, it can easily be shown that the following broadcasting process generates a translation invariant Gibbs measure $\nu$ on $T_\Delta$: first choose the spin at the root $\rho$ according to the probability vector $\alpha$. The spin of the root is then propagated along the edges of the tree; if $u$ is the parent of $v$ in the tree, then

$$\nu(\sigma(v) = j | \sigma(u) = i) = M_{ij}.$$ 

It is straightforward to check that each vertex has marginal spin distribution $\alpha$.

For a fixpoint of the depth two tree recursions (8), a slight modification of the above argument is possible. Namely, for $r = (R_1, \ldots, R_q), c = (C_1, \ldots, C_q)$, define the probability vectors $\alpha = (\alpha_1, \ldots, \alpha_q), \beta = (\beta_1, \ldots, \beta_q)$ given by

$$\alpha_i = \frac{R_i \sum_{j=1}^q B_{ij} C_j}{\sum_{i,j} B_{ij} R_i R_j}, \quad \beta_j = \frac{C_j \sum_{i=1}^q B_{ij} R_i}{\sum_{i,j} B_{ij} R_i C_j},$$

and consider the following $q \times q$ matrices: $M^+ = (M^+_{ij})_{i,j \in \{q\}}$ whose $(i,j)$-entry is given by $B_{ij} C_j / \sum_{j=1}^q B_{ij} C_j$, and $M^- = (M^-_{ij})_{i,j \in \{q\}}$ whose $(i,j)$-entry is given by $B_{ij} R_j / \sum_{j=1}^q B_{ij} R_j$. As before, it is immediate to verify that $M^+, M^-$ are stochastic and by construction
$\alpha M^+ = \beta$ and $\beta M^- = \alpha$. There are two possible ways now to define the broadcasting process, which are symmetric up to interchanging $\alpha, \beta$ and $M^+, M^-$. We describe explicitly one of the two: first choose the spin at the root $\rho$ according to the probability vector $\alpha$. The spin of the root is then propagated along the edges of the tree; if $u$ is the parent of $v$ in the tree and $v$ has odd distance from the root of the tree, then

$$\nu(\sigma(v) = j \mid \sigma(u) = i) = M^+_{ij}.$$  

Otherwise,

$$\nu(\sigma(v) = j \mid \sigma(u) = i) = M^-_{ij}.$$  

As in the translation-invariant case, it is straightforward to check that each vertex at odd level has marginal distribution $\beta$, while each vertex at even level has marginal distribution $\alpha$.

### 1.3 Phase Transitions on Random Regular Graphs

The behavior of spin systems on sparse random graphs has been the subject of intensive study in statistical physics, probability and probabilistic combinatorics, see for example [11]. We will use such graphs as gadgets for our inapproximability results. In this section, we make the crucial connection between the Gibbs distribution of such graphs and Gibbs measures, laying down the most technical part of our work.

There is a well-known connection between sparse random graphs and random trees (see for example [10]). This connection is particularly simple for random $\Delta$-regular graphs. Namely, a random $\Delta$-regular graph converges locally to the infinite $\Delta$-regular tree. We will not give the general definition of local convergence for graphs but rather what it means in our setting. Let $v$ be a random vertex of a $\Delta$-regular graph $G$ with $n$ vertices and let $t \geq 1$ be an arbitrary integer. The $t$-step neighborhood of $v$ is the set of vertices in $G$ whose graph distance from $v$ is at most $t$. The local convergence of a random $\Delta$-regular graph to $T_\Delta$ can be stated as follows: for all $n$ sufficiently large, with probability $1 - o(1)$ over the choice of $v$ and the graph $G$, the $t$-step neighborhood of $v$ is isomorphic to the $t$-step neighborhood of the root of $T_\Delta$. In other words, for all but a vanishing fraction of vertices of a random
Δ-regular graph $G$, the local neighborhood of a vertex looks like a complete tree. Another
way of expressing the above is that the number of short cycles (i.e., constant length, not
depending on $n$) is $o(n)$.

Given this property, it is reasonable to expect that the analysis of the Gibbs distribution
on random Δ-regular graphs would be connected with the infinite volume Gibbs distribution
on $\mathbb{T}_\Delta$. However, whether this connection actually holds turns out to depend on the spin
system. Let us first explain in more detail how one can obtain an alignment between the
two settings and then what can go wrong.

We will restrict our attention on two classes of graph distributions, random Δ-regular
graphs and random bipartite Δ-regular graphs, which we will use for our inapproximability
results. The approach we will ultimately describe for analyzing the Gibbs distribution on
random graphs will be much more general for the class of random bipartite Δ-regular graphs,
so we will focus on this distribution first and discuss extensions to the random Δ-regular
graph case afterwards.

For a $q$-spin system with interaction matrix $B$, our goal is to understand the Gibbs
distribution on a random Δ-regular bipartite graph $G = (V, E)$ (with bipartition $V = V_1 \cup V_2$) by looking at the distribution of spin values in $V_1$ and $V_2$. Let $n = |V_1| = |V_2|$. For
a configuration $\sigma : V \to [q]$, we denote the set of vertices assigned spin $i$ by $\sigma^{-1}(i)$. For
$q$-dimensional probability vectors $\alpha, \beta$, let

$$\Sigma^{\alpha, \beta} = \{ \sigma : V \to \{1, \ldots, q\} \mid |\sigma^{-1}(i) \cap V_1| = \alpha_i n, |\sigma^{-1}(i) \cap V_2| = \beta_i n \text{ for } i = 1, \ldots, q\},$$

that is, configurations in $\Sigma^{\alpha, \beta}$ assign $\alpha_i n$ and $\beta_i n$ vertices in $V_1$ and $V_2$ the spin value $i$, respectively. For example, in the case of the hard-core model, the set $\Sigma^{\alpha, \beta}$ would correspond
to the independent sets of $G$ which have $\alpha n$ vertices in $V_1$ and $\beta n$ vertices in $V_2$, upon
identifying $\alpha, \beta$ with the scalars $\alpha, \beta$ since for 2-spin systems we only need two variables to
capture the spin frequencies. Our interest will be in the total weight $Z^{\alpha, \beta}_G$ of configurations
in $\Sigma^{\alpha, \beta}$, namely

$$Z^{\alpha, \beta}_G = \sum_{\sigma \in \Sigma^{\alpha, \beta}} w_G(\sigma).$$

What would be the pairs $\alpha, \beta$ with the largest $Z^{\alpha, \beta}_G$? Let us give a high level motivation to
this question. We expect that for sufficiently large $n$, the $\alpha, \beta$ with the largest $Z^\alpha_\beta_G$ are the only ones we really see in the Gibbs distribution of $G$, since the partition function of $G$ is just a sum of a polynomial (in $n$) number of $Z^\alpha_\beta_G$ which are typically exponential in $n$. Thus, pairs $\alpha, \beta$ which maximize $Z^\alpha_\beta_G$ should correspond in some sense to equilibrium states in the Gibbs distribution of the random graph. A more precise mathematical formulation of what we are trying to do is to establish the modes in the vertex empirical distribution of the $q$-spin system on a random $\Delta$-regular bipartite graph.

To go one step further, let us look again at the example of the hard-core model and use the view with the local tree-like structure of the graph to speculate how the equilibrium might look. As previously, we consider independent sets with a prescribed number of $\alpha n, \beta n$ vertices in $V_1, V_2$. In a random such configuration, a vertex $v \in V_1$ would typically see a complete tree whose vertices at odd levels are occupied with probability $\beta$ and at even levels are occupied with probability $\alpha$. Thus, one would expect to see in the limit $n \to \infty$ a semi-translation invariant Gibbs measure of the infinite $\Delta$-regular tree. The reader may have observed that this view is on a shaky ground; the phrase “in a random such configuration” implicitly assumes that a random configuration in the hard-core model distribution is decorellated from the random graph. Despite this deficit of the argument, we now have an overview of what we would like to formalize.

A great portion of this thesis is targeted to establish the picture above for general spin systems on random $\Delta$-regular bipartite graphs. To do this, and following previous approaches for the hard-core model [43], we will look at the moments of $Z^\alpha_\beta_G$ with respect to the distribution of the random $\Delta$-regular bipartite graph, from hereon denoted by $G$.

For the next two subsections, we will focus on analyzing the leading terms of the first and second moments of $Z^\alpha_\beta_G$, namely

$$\Psi_1(\alpha, \beta) = \Psi_1^B(\alpha, \beta) := \lim_{n \to \infty} \frac{1}{n} \log \mathbb{E}_G[Z^\alpha_\beta_G],$$

$$\Psi_2(\alpha, \beta) = \Psi_2^B(\alpha, \beta) := \lim_{n \to \infty} \frac{1}{n} \log \mathbb{E}_G[(Z^\alpha_\beta_G)^2].$$

The function $\Psi_1$ will be used to make connections to the depth two recursions (8) and hence semi-translation invariant Gibbs measures on $T_\Delta$. The function $\Psi_2$ will be used to identify
those \((\alpha, \beta)\) for which \(Z_{G}^{\alpha, \beta}\) is asymptotically independent from the choice of the random graph.

### 1.3.1 First Moment

To start, denote the leading term of the first moment of \(Z_{G}^{\alpha, \beta}\) as:

\[
\Psi_{1}(\alpha, \beta) = \Psi_{1}^{B}(\alpha, \beta) := \lim_{n \to \infty} \frac{1}{n} \log \mathbb{E}_{\varphi} [Z_{G}^{\alpha, \beta}],
\]

We will be interested in the global maximizers of \(\Psi_{1}\), which (at least in expectation) capture the configurations which have the largest contribution in the partition function of a random \(\Delta\)-regular bipartite graph as \(n \to \infty\). This motivates the following definition.

**Definition 5.** For a \(q\)-spin system with interaction matrix \(B\), a dominant phase is a pair \((\alpha, \beta)\) of \(q\)-dimensional probability vectors which maximize \(\Psi_{1}(\alpha, \beta)\).

Now, we have a concrete function whose maxima hopefully capture the equilibrium states of a random bipartite \(\Delta\)-regular graph \(G\), we will address this point later. Prior to that, we first look at the critical points of \(\Psi_{1}\) to get a better understanding of the dominant phases. The following definition will help to make the picture more clear.

**Definition 6.** For a \(q\)-spin system with interaction matrix \(B\), a phase is a pair \((\alpha, \beta)\) of \(q\)-dimensional probability vectors which is a critical point of \(\Psi_{1}(\alpha, \beta)\).

A conceptual observation made in [43] in the context of the hard-core model was that the phases of a random \(\Delta\)-regular bipartite graph correspond to the semi-translation invariant Gibbs measures on \(T_{\Delta}\). This extends rather easily to the general \(q\)-spin model as well, see Section 3.2.2 for a derivation in our setting. In particular, we restate for the reader’s convenience the depth two tree recursions on \(T_{\Delta}\).

\[
\hat{R}_{i} \propto \left( \sum_{j=1}^{q} B_{ij} C_{j} \right)^{\Delta-1} \quad \text{and} \quad \hat{C}_{j} \propto \left( \sum_{i=1}^{q} B_{ij} R_{i} \right)^{\Delta-1}. \tag{8}
\]

The phase \((\alpha, \beta)\) corresponding to a fixpoint \((R_{1}, \ldots, R_{q}, C_{1}, \ldots, C_{q})\) of the tree recursions is given by (9), which we restate here for concreteness.

\[
\alpha_{i} = \frac{R_{i} \sum_{j=1}^{q} B_{ij} C_{j}}{\sum_{i,j} B_{ij} R_{i} C_{j}}, \quad \beta_{j} = \frac{C_{j} \sum_{i=1}^{q} B_{ij} R_{i}}{\sum_{i,j} B_{ij} R_{i} C_{j}}. \tag{9}
\]
Recall here that the vectors $\alpha, \beta$ are the marginal spin distributions of even and odd vertices in the semi-translation invariant Gibbs measure on $T_\Delta$ corresponding to the fixpoint $(R_1, \ldots, R_q, C_1, \ldots, C_q)$ of (8), cf. Section 1.2.3.1. This establishes a firm connection between critical points of $\Psi_1$ and Gibbs measures on $T_\Delta$.

However, even this level of understanding is not sufficient for our purposes. The reason being, that the critical points of a function $f$ can be local minima, local maxima or saddle points of the function. We need hence a more refined picture to restrict our attention to the phases that can be dominant phases. This investigation will also allow us to connect the semi-translation invariant uniqueness threshold with the Jacobian stability of fixpoints.

To obtain a handle on the local maxima of a function, we use the Hessian criterion: a critical point $x \in \mathbb{R}^t$ of a function $f : \mathbb{R}^t \to \mathbb{R}$ is a local maximum of $f$ if the Hessian matrix of $f$ at $x$ is negative definite. When the Hessian criterion is true, we call the critical point a Hessian local maximum. In Section 3.4, we show the following connection between the stability of the tree recursions and Hessian local maxima of $\Psi_1$.

**Theorem 2.** Jacobian attractive fixpoints of the depth two tree recursions (8) correspond to Hessian local maxima of $\Psi_1$. Moreover, if $B$ is ergodic (irreducible and aperiodic), Hessian local maxima of $\Psi_1$ correspond to Jacobian attractive fixpoints of the depth two tree recursions.

In particular, we have the following straightforward corollary.

**Corollary 3.** For every ergodic $B$ (irreducible and aperiodic), a phase of a random $\Delta$-regular bipartite graph is a local maximum of $\Psi_1$ iff the corresponding fixpoint of the depth two tree recursions is Jacobian attractive.

Before concluding this section, let us comment briefly on the restriction in the second part of Theorem 2, which requires $B$ to be irreducible and aperiodic. Irreducibility is a natural condition on the spin system; if not, the spin system may be decomposed into irreducible spin systems and everything applies. For connected graphs, the partition function of the initial spin system is just the sum of “sub-spin” systems. Thus, the irreducibility condition merely excludes degenerate cases. The aperiodicity condition is also kind of a
degenerate one, in the following sense. A periodic spin system must have period two (since $B$ is symmetric) and hence such a spin system is only interesting on bipartite graphs (otherwise the partition function is zero). Thus, the condition is rather an artifact of studying the spin system on a bipartite graph (for random regular graphs for example the condition may be immediately dropped). By restricting to appropriate subspaces, one can still show an analog of Theorem 2. We do not pursue this path here since for spin systems studied in statistical physics and computer science, it is usually the case that the system remains interesting on non-bipartite graphs, cf. the spin systems in Section 1.1.

1.3.2 Second Moment

Having established a connection between dominant phases and Gibbs measures on $T_{\Delta}$, we next come to perhaps the most intriguing aspect of establishing that the dominant phases are indeed “equilibria” of a random $\Delta$-regular graph. We first explain why the first moment argument above is not sufficient. Using Markov’s inequality, one can easily show that only dominant phases can have significant contribution to the partition function of $G$. This information alone however is insufficient, since we would like a lower bound for the contribution of dominant phases to the partition function to argue that the dominant phases correspond to natural equilibrium states of the random graph (with high probability over the choice of the graph). Ideally, the lower bound would be in terms of the expectation, and we are naturally led to consider the second moment of $Z_G^{\alpha, \beta}$.

The well known second moment method establishes the concentration of a random variable $X$ around its expectation $E[X]$, provided that the ratio $E[X^2]/(E[X])^2$ is close to 1. While this direct approach will not work for us, there is a substitute of the method, known as the small subgraph conditioning method, which works extremely well for probability spaces corresponding to random $\Delta$-regular graphs. The method still needs to argue however about the asymptotic order of the second moment, in our case $E_G[(Z_G^{\alpha, \beta})^2]$.

As a necessary step, we need to consider first the leading term of the second moment, which we recall that it is given by

$$
\Psi_2(\alpha, \beta) = \Psi_2^B(\alpha, \beta) := \lim_{n \to \infty} \frac{1}{n} \log E_G\left[(Z_G^{\alpha, \beta})^2\right].
$$
The following theorem relates the second moment to the first moment, for any spin system on random bipartite $\Delta$-regular graphs. The proof is given in Section 3.3.

**Theorem 4.** For any spin system, for all $\Delta \geq 3$,

$$\max_{\alpha, \beta} \Psi_2(\alpha, \beta) = 2 \max_{\alpha, \beta} \Psi_1(\alpha, \beta).$$

In particular, for every dominant phase $(\alpha, \beta)$, it holds that $\Psi_2(\alpha, \beta) = 2\Psi_1(\alpha, \beta)$.

Theorem 4 suggests that for a dominant phase $(\alpha, \beta)$, $E_G[(Z_G^{\alpha, \beta})^2]/(E_G[Z_G^{\alpha, \beta}])^2$ should be asymptotically equal to a constant and hints that $Z_G^{\alpha, \beta}$ should be close to its expectation. Though certain difficulties do emerge (the implicit constant turns out to be a constant greater than 1, see Section 1.3.3 for a more thorough discussion), it all comes down to proving Theorem 4.

Second moment arguments analogous to the one given in Theorem 4 tend to be difficult. To illustrate the difficulty, let us give the development of the proof for Theorem 4 in the case of the hard-core model. This was first done in [43], where they showed the equality $\Psi_2(\alpha, \beta) = 2\Psi_1(\alpha, \beta)$ for the dominant phase at $\lambda = \lambda_c(T_\Delta)$ for all $\Delta \geq 3$. By a convexity/continuity argument, they were able to conclude the existence of $\varepsilon(\Delta) > 0$ such that the same equality holds for $\lambda_c(T_\Delta) < \lambda < \lambda_c(T_\Delta) + \varepsilon(\Delta)$. Their argument was used in the seminal inapproximability results of [49], which due to the same technical reason were only obtained under the same condition and the interesting subcase $\lambda = 1$, $\Delta = 6$. The analysis of [43] was extended in [16] for certain regimes of $\lambda, \Delta$ in a way that was sufficient to conclude the inapproximability results for $\Delta = 3$ and $\Delta \geq 6$ for all $\lambda > \lambda_c(T_\Delta)$. After that, in [17] the remaining cases $\Delta = 4, 5$ were settled by a somewhat easier analysis which applied to a subclass of general antiferromagnetic 2-spin systems. Simultaneously, [50] managed to circumvent the second moment analysis for the hard-core model (and general 2-spin systems) by a different approach. Needless to say that the reason why the second moment approach seemed to work for random bipartite $\Delta$-regular graphs, even in the 2-spin case, remained elusive. To add more to this mystery, it was well-known that the second moment approach fails for random regular graphs after a certain threshold.
The analysis for the proof of Theorem 4, which appeared in [18], is surprisingly simple given the difficulty in the previous approaches even in the rather restricted setting of 2-spin systems. There are two key ideas: the first one is the reformulation of the function $\Psi_1(\alpha, \beta)$ with an auxiliary function $\Phi(r, c)$. The reformulation is such that the maximum of $\Psi_1$ over $\alpha, \beta$ equals the maximum $\Phi$ over $r, c$ (in fact, there is even a correspondence among the maximizers which we need to apply the small subgraph conditioning method). At the same time, the maximum of $\Phi$ can easily be expressed as a matrix norm of the interaction matrix $B$. The second key idea is more of an observation: the second moment can be interpreted as a paired spin model, i.e., a $q^2$-spin system with interaction matrix $B \otimes B$, where $\otimes$ denotes the Kronecker product. Then the maximum of $\Psi_2$ is captured by the norm of the matrix $B \otimes B$. It then comes down to connect the two norms, at which point we can utilize a result of Bennett [3], stating that the relevant norms are multiplicative over tensor product. For concreteness, we next give in more detail the connection between $\Psi_1$ and $\Phi$.

First, we need to define the function $\Phi$. We will need to set up some notation. Recall that the $p$-norm of a vector $x \in \mathbb{R}^n$ is given by

$$
\|x\|_p := \left( \sum_{i=1}^{n} |x_i|^p \right)^{1/p}.
$$

We will use the subordinate matrix norm (also known as the induced matrix norm) which will be denoted as $\|\cdot\|_{p \to q'}$ (this is different than the usual notation $\|\cdot\|_{p \to q}$ used in the literature, since we have reserved $q$ for the number of spins) and is defined as:

$$
\|A\|_{p \to q'} = \max_{\|x\|_p = 1} \|Ax\|_{q'}.
$$

Note that if $A$ has non-negative entries then one can restrict the maximization to $x$ with non-negative entries. A well-known example of an induced norm is the spectral norm $\|\cdot\|_{2 \to 2}$.

Let $p = \Delta/(\Delta - 1)$. For non-negative $q$-dimensional vectors $r := (R_1, \ldots, R_q), c := (C_1, \ldots, C_q)$, define $\Phi(r, c)$ by:

$$
\exp \left( \Phi(r, c)/\Delta \right) = \frac{r^\top Bc}{\|r\|_p \|c\|_p}.
$$

The maximum of $\Phi$ can be compactly expressed in terms of matrix norms, as follows:

$$
\max_{r,c} \exp \left( \Phi(r, c)/\Delta \right) = \max_c \max_r \frac{r^\top Bc}{\|r\|_p \|c\|_p} = \max_c \frac{\|Bc\|_\Delta}{\|c\|_p} = \|B\|_{p \to \Delta}, \quad (10)
$$
where the second equality follows from matrix norm duality (see for example [23]).

The following theorem connects tree recursions, the function $\Phi$ and the function $\Psi_1$.

The proof is given in Section 3.2.

**Theorem 5.** There is a one-to-one correspondence between the fixpoints of the tree recursions and the critical points of $\Phi$ (both considered for $R_i \geq 0, C_j \geq 0$ in the projective space, that is, up to scaling by a constant).

The following transformation $(r, c) \mapsto (\alpha, \beta)$ given by:

$$
\alpha_i = \frac{R_i^{\Delta/(\Delta-1)}}{\sum_i R_i^{\Delta/(\Delta-1)}} \quad \text{and} \quad \beta_j = \frac{C_j^{\Delta/(\Delta-1)}}{\sum_j C_j^{\Delta/(\Delta-1)}} \tag{11}
$$

yields a one-to-one-to-one correspondence between the critical points of $\Phi$ and the critical points of $\Psi_1$ (in the region defined by $\alpha_i \geq 0, \beta_j \geq 0$ and $\sum_i \alpha_i = 1, \sum_j \beta_j = 1$).

Moreover, for the corresponding critical points $(r, c)$ and $(\alpha, \beta)$ one has

$$
\Phi(r, c) = \Psi_1(\alpha, \beta). \tag{12}
$$

Finally, for ergodic $\mathbf{B}$ (irreducible and ergodic), the local maxima of $\Phi$ and $\Psi_1$ happen at the critical points (that is, there are no local maxima on the boundary).

The first item states that the critical points of $\Phi$ are given by the tree recursions; this follows from a straightforward differentiation. Equation (11) gives the correspondence between fixpoints of the tree recursions and the critical points of $\Psi_1$; note that this equation is seemingly different than (9), though the two expressions can easily be seen to be equivalent using that $(r, c)$ are fixpoints of (8). Equation (12) is the most important piece for the second moment analysis; it asserts that the values of the functions $\Psi_1$ and $\Phi$ at the corresponding critical points are equal. Since the final item guarantees that the maxima of $\Psi_1, \Phi$ happen at their critical points, we obtain that they have the same maximum value yielding the matrix norm formulation of $\Psi_1$ we wanted. We remark that the last point can also be obtained even when the maximum happens at the boundary; the restriction of ergodicity imposed on $\mathbf{B}$ is to make the connection more transparent.
1.3.3 Gibbs distribution of a random graph and short cycles

Theorem 4 establishes that for a dominant phase \((\alpha, \beta)\) the exponential order of the second moment of \(Z_G^{\alpha, \beta}\) is twice the exponential order of the first moment of \(Z_G^{\alpha, \beta}\). The question we would like to address now is whether this can be used to establish concentration for \(Z_G^{\alpha, \beta}\). In the ideal scenario, we would be able to apply Chebyshev’s inequality to get immediately a sharp concentration result. For this method to be successful, it must be the case that the ratio \(\frac{E_G[(Z_G^{\alpha, \beta})^2]}{(E_G[Z_G^{\alpha, \beta}])^2}\) converges asymptotically to 1. An intensive calculation of the asymptotic ratio, yields however

\[
\lim_{n \to \infty} \frac{E_G[(Z_G^{\alpha, \beta})^2]}{(E_G[Z_G^{\alpha, \beta}])^2} = C > 1,
\]

for a constant \(C\) depending on the interaction matrix \(B\) and \(\Delta\), see Lemma 40 for an explicit form. Thus, the direct second moment method only yields the existence of a graph \(G\) where \(Z_G^{\alpha, \beta}\) is comparable to its expected value. This is for several reasons bad: first, it does not allow to get a statement which holds with high probability over the choice of the random graph; second, if there exist multiple dominant phases, i.e., the \(q\)-spin system is in the semi-translation invariant non-uniqueness regime of \(T_\Delta\), we are not guaranteed that the dominant phases coexist in at least one graph, which is a crucial component in utilizing the uniqueness phase transition. Fortunately, there exists a well-established method to deal with this apparent (13) failure of the second moment method, known as the small subgraph conditioning method.

The small subgraph conditioning method was introduced in [46] to prove that a random \(\Delta\)-regular contains asymptotically almost surely (a.a.s.) a Hamilton cycle. Roughly speaking, the method provides a way to get a.a.s results when the second moment method fails, in the particular case (though common in the random regular graph setting) where the ratio of the second moment of a variable to the first moment squared converges to a constant strictly greater than 1. The method was first used to analyze spin models on random regular graphs in [43] and was subsequently used in [49, 17]. The principle behind the method is that the variance of \(Z_G^{\alpha, \beta}\) comes from the presence of short cycles, which as we discussed in Section 1.3 are few, but still appear with non-zero probability (asymptotically
with \( n \), they follow the Poisson distribution).

In our setting, this comes about almost naturally. We have already seen that \( \mathbb{E}_G[Z^\alpha_G] \) is determined by the Gibbs measure on the infinite \( \Delta \)-regular tree. On the other hand, we do expect a deviation from the expectation since a graph \( G \sim \mathcal{G} \) does have \( o(n) \) vertices which are contained in constant sized cycles. Thus, it is reasonable to expect that \( Z^\alpha_G \) fluctuates from its expectation. It is equally reasonable to expect the fluctuations to depend on the presence of small cycles which occur with small but non-zero probability. The surprising aspect of (14), a consequence of applying the small subgraph conditioning method, is that there is an explicit handle on these fluctuations.

The following lemma is a special case of the slightly stronger Lemma 33 which will help us to make the above explicit. The proof is given in Section 4.2.1.

**Lemma 6.** Suppose that \((\alpha, \beta)\) is a dominant phase on random bipartite \( \Delta \)-regular graph, which corresponds to a Jacobian attractive fixpoint of the tree recursions. Let \( G \sim \mathcal{G} \) and denote by \( X_{ni} \), \( i = 1, 2, \ldots \), the number of cycles of length \( 2i \) in \( G \). There exist random variables \( W_{mn} \), a deterministic function of \( X_{1n}, X_{2n}, \ldots, X_{mn} \), such that for every \( \varepsilon > 0 \)

\[
\lim_{m \to \infty} \limsup_{n \to \infty} \Pr_G\left( \left| \frac{Z^\alpha_G}{\mathbb{E}_G[Z^\alpha_G]} - W_{mn} \right| > \varepsilon \right) = 0,
\]

(14)

There also exists a positive constant \( c > 0 \) such that \( W_{mn} > c \) uniformly in \( m, n \).

The rather unintuitive limit in (96) should be understood as follows: if we let \( m, n \) sufficiently large, the random variable \( \frac{Z^\alpha_G}{\mathbb{E}_G[Z^\alpha_G]} \) is well-approximated by the random variables \( W_{mn} \), with large probability over the choice of the random graph. Lemma 14 (or rather its slightly strengthened version in Lemma 33) will be crucial for proving the properties of the gadget in our inapproximability results since it will allow us to tie \( Z^\alpha_G \) to the underlying graph. Thus, even when there exist multiple dominant phases, we can hope to compare their contribution to the partition function by understanding the corresponding random variables \( W_{mn} \).
1.3.4 Extensions to Random Regular Graphs

In this section, we discuss extensions of our techniques to random $\Delta$-regular graphs. First, a word of caution; we cannot possibly hope to get as general results as in previous sections. For example, in the $k$-colorings model on random $\Delta$-regular graphs the second moment approach cannot possibly work when the number of colors is less than $\frac{\Delta}{2\log\Delta}(1+o(1))$, since this is with high probability the chromatic number of the random graph. However we do identify two cases where the approach works well. The most important one is in the context of ferromagnetic spin systems. Let us first the notion of ferromagnetism we use.

**Definition 7.** A model is called *ferromagnetic* if $B$ is positive definite. Equivalently we have that all of its eigenvalues are positive and also that

$$B = \hat{B}^\top \hat{B},$$

for some $q \times q$ matrix $\hat{B}$.

The most alluring aspect of this definition is that for a ferromagnetic model, neighboring vertices prefer to have the same spin, matching the intuition with the 2-spin setting. More generally, we have the following simple application of the Cauchy-Schwarz inequality. If $B$ is ferromagnetic, then for probability vectors $z_1, z_2$, it holds that

$$(z_1^\top B z_1)(z_2^\top B z_2) \geq (z_1^\top B z_2)^2,$$

In particular, if we plug in the inequality (236) the vectors with a single 1 in the positions $i$ and $j$ respectively, we obtain that any two spins $i, j$ induce a ferromagnetic two-spin system. The definition is discussed more thoroughly in Section 8.1.2.

To state our results for ferromagnetic models, let us present briefly the slightly different setting. Let $G = (V, E)$ be a random $\Delta$-regular graph with $n = |V|$. For a $q$-dimensional probability vector $\alpha$, denote by $\Sigma^\alpha$ the set of configurations $\sigma$ which assign to $\alpha_i n$ vertices the spin $i$ for each $i \in [q]$. Let

$$Z^\alpha_G = \sum_{\sigma \in \Sigma^\alpha} w_G(\sigma).$$

We again study $Z^\alpha_G$ by looking at the moments $E_G[Z^\alpha_G]$ and $E_G[(Z^\alpha_G)^2]$, where the expectation is over the distribution of the random $\Delta$-regular bipartite graph $G$, from hereon
denoted by \(\mathcal{G}\) (no confusion should arise with the notation for bipartite random \(\Delta\)-regular graphs).

Denote the leading term of the first and second moments as:

\[
\Psi_1(\alpha) = \Psi_1^B(\alpha) := \lim_{n \to \infty} \frac{1}{n} \log \mathbb{E}_\mathcal{G}[Z^\alpha_G].
\]

\[
\Psi_2(\alpha) = \Psi_2^B(\alpha) := \lim_{n \to \infty} \frac{1}{n} \log \mathbb{E}_\mathcal{G}[(Z^\alpha_G)^2].
\]

Dominant phases are vectors \(\alpha\) which are maximizers of \(\Psi_1(\alpha)\). Analogously to Theorem 2, we prove the following in Section 8.3.

**Theorem 7.** For a ferromagnetic model, Jacobian attractive fixpoints of the (depth one) tree recursions are in one-to-one correspondence with the Hessian local maxima of \(\Psi_1\).

Also, we obtain the analogue of Theorem 4 for ferromagnetic models on random regular graphs. The reason that this is possible in the case of ferromagnetic Potts model is the Cholesky decomposition in Definition 7, which allows us to formulate the maximum of the first moment as a matrix norm (which in general is not possible).

**Theorem 8.** For a ferromagnetic model,

\[
\max_\alpha \Psi_2(\alpha) = 2 \max_\alpha \Psi_1(\alpha).
\]

Specifically, for dominant phases \(\alpha\), \(\Psi_2(\alpha) = 2\Psi_1(\alpha)\).

The other interesting case where our methods apply on random \(\Delta\)-regular graphs is when the \(q\)-spin system lies in the semi-translation invariant uniqueness regime of \(\mathbb{T}_\Delta\). The following theorem establishes the so-called Bethe prediction. Similar flavored results are well-known in the literature (assuming uniqueness), the most general to the best of our knowledge appear to be in [12].

**Theorem 9.** Let \(\mathbf{B}\) be the interaction matrix of a spin system such that \(Z_G > 0\) for all \(\Delta\)-regular graphs. Assume that there exists a unique semi-translation invariant Gibbs measure on \(\mathbb{T}_\Delta\) and the corresponding fixpoint of the tree recursions (7) is Jacobian attractive. Provided that the matrix \(\mathbf{B}\) is regular (non-zero determinant),

\[
\lim_{n \to \infty} \frac{1}{n} \mathbb{E}_\mathcal{G} [\log Z_G] = \lim_{n \to \infty} \frac{1}{n} \log \mathbb{E}_\mathcal{G} [Z_G].
\]
The assumption $Z_G > 0$ for all $\Delta$-regular graphs is to avoid pathological cases where $\log Z_G \equiv -\infty$ in which case the quantities are not well-defined. It is satisfied by many classes of models, e.g., permissive models (cf. Section 1.1.1), such as the hard-core and antiferromagnetic Potts models, or even non-permissive, such as $k$-colorings when $k \geq \Delta + 1$. Finally, the restriction that $B$ is regular is to ensure that we can apply the small subgraph conditioning method (see the relevant Lemma 28).

1.4 The Complexity Lens

1.4.1 Preliminaries

We will be interested in the following counting problem.

**Parameters:** integer $q \geq 2$, $q \times q$ symmetric matrix $B$ with non-negative entries.

**Name:** $\#\text{PARTITIONFUNCTION}(q, B)$.

**Input:** A graph $G$.

**Output:** The partition function $Z_G$ for the $q$-spin system specified by the interaction matrix $B$.

The input of $\#\text{PARTITIONFUNCTION}(q, B)$ will often be restricted to $\Delta$-regular graphs or graphs with maximum degree $\Delta$, where $\Delta \geq 3$ is a fixed constant. This will be clear from context.

Exact computation of $\#\text{PARTITIONFUNCTION}(q, B)$ is $\#P$-complete unless the matrix $B$ has rank 1 [8]. When $B$ has 0,1 entries, this is known to hold even for graphs of bounded degree [15], and it is reasonable to expect that $\#\text{PARTITIONFUNCTION}(q, B)$ is $\#P$-complete even when restricted to graphs of maximum degree $\Delta$, for all $\Delta \geq 3$. We will thus be interested in efficient approximations of $\#\text{PARTITIONFUNCTION}(q, B)$; below we give a formal description of the class of algorithms that will be of interest to us.

Let $f : \Sigma^* \to \mathbb{R}$, where $f$ is a function we are interested in computing and $\Sigma^*$ is an encoding of the instances. A *polynomial-time randomized approximation scheme* (PRAS) for $f$ is a randomized algorithm that takes as input a pair $(x, \varepsilon) \in \Sigma^* \times (0, 1)$ and outputs in polynomial time (in the length $|x|$ of the input) the value of a random variable $Y$ supported on rational numbers which satisfies $\Pr[|Y - f(x)| \leq \varepsilon |f(x)|] \geq 3/4$. A *fully polynomial-time*
randomized approximation scheme (FPRAS) for $f$ has the same guarantees as a PRAS, but the algorithm is required to run in polynomial time both in the length $|x|$ and $1/\varepsilon$. A PTAS and an FPTAS are the deterministic analogues of PRAS and FPRAS, respectively.

We will also need to compare the relative complexity of approximating the partition functions in two different spin systems. This notion was introduced in [14]. Let $f, g : \Sigma^* \to \mathbb{R}$. An approximation-preserving reduction (AP – reduction) from $f$ to $g$ is an FPRAS for $f$ that has oracle access to an FPRAS for $g$; moreover, on input $(x, \varepsilon) \in \Sigma^* \times (0, 1)$, all oracle calls to $g$ should be pairs $(y, \delta) \in \Sigma^* \times (0, 1)$, where $|y|$ is polynomial in $|x|, \varepsilon^{-1}$ and $\delta$ is polynomial in $|x|, \varepsilon$.

1.4.2 A Sharp Dichotomy for Antiferromagnetic 2-spin systems

A striking computational transition was established for the problem of approximating the partition function in the hard-core model. Namely, Weitz [52] gave an FPTAS for the partition function of graphs with maximum degree $\Delta$ when $\Delta$ is constant and $\lambda < \lambda_c(T_\Delta)$. On the other hand, Sly [49] proved (extended in [16, 17, 50] and also Theorem 10 in this thesis) that, unless $NP = RP$, for every $\Delta \geq 3$ and $\lambda > \lambda_c(T_\Delta)$, there does not exist an FPRAS for the partition function on graphs with maximum degree $\Delta$. In fact, it was proved in [50] that the intractability result remains true even within an exponential factor of approximation.

The results of [52] and [49] established for the first time a strong connection between computational complexity and phase transitions. The infinite $\Delta$-regular tree was identified to be the worst case graph for the persistence of long range-correlations in the case of the hard-core model. This was later extended to antiferromagnetic 2-spin systems; recall that these are systems where neighboring vertices are favored to have different spins. For the algorithmic side see [47, 32], and for the intractability side see [50]. As a straightforward application of our upcoming general theorem 14, we can also easily cover the computational hardness regime in the 2-spin setting.

**Theorem 10.** Let $\Delta \geq 3$. For an antiferromagnetic 2-spin system in the non-uniqueness regime of $T_\Delta$, unless $NP=RP$, there is no FPRAS for approximating the partition function.
for triangle free $\Delta$-regular graphs. Moreover, there exists $\varepsilon = \varepsilon(q, \Delta)$ such that, unless NP=RP, one cannot approximate the partition function within a factor $2^\varepsilon n$ for triangle-free $\Delta$-regular graphs (where $n$ is the number of vertices).

For 2-spin antiferromagnetic models, this establishes a beautiful picture connecting the computational complexity of approximating the partition function to statistical physics phase transitions in the infinite tree.

Before proceeding, we remark that for ferromagnetic 2-spin systems, on regular graphs there is an FPRAS for estimating the partition function [21, 27] for all parameters (for graphs of maximum degree $\Delta$, the picture is more complicated, see [34]).

### 1.4.3 NP Hardness Results For Colorings And Antiferromagnetic Potts Model

The picture for multi-spin systems (systems with $q > 2$ possible spins for vertices) is much less clear; the above approaches for 2-spin systems do not extend to multi-spin models in a straightforward manner. We aim to establish the analog of the above inapproximability results for the colorings problem, namely, NP-hardness in the tree non-uniqueness region. Our techniques and results generalize to a broad class of antiferromagnetic spin systems.

For the colorings problem, even understanding the uniqueness threshold is challenging. Jonasson [29] established uniqueness when $k \geq \Delta + 1$, and it is easy to show non-uniqueness when $k \leq \Delta$ since a fixed coloring on the leaves can “freeze” the internal coloring. For 2-spin systems uniqueness can be characterized by the existence of multiple solutions of a certain system of equations (8), called tree recursions, see Section 1.4.4 for additional explanation. In statistical physics terminology the solutions to these equations correspond to semi-translation invariant measures on the infinite tree $T_\Delta$. For colorings the uniqueness threshold and the semi-translation invariant uniqueness threshold no longer coincide. In particular, Brightwell and Winkler [7] established, for semi-translation invariant measures, uniqueness when $k \geq \Delta$ and non-uniqueness when $k < \Delta$.

We prove, for even $k$, that it is NP-hard to approximate the number of colorings (in other words, NP-hard to approximate the partition function) when there is non-uniqueness of semi-translation invariant Gibbs measures on $T_\Delta$ which corresponds to $k < \Delta$. Moreover,
our result proves hardness for the class of triangle-free $\Delta$-regular graphs. Hence, our result is particularly interesting in the region $k = \Omega(\Delta/\log \Delta)$ since a seminal result of Johansson [28, 40] shows that all triangle-free graphs are colorable with $O(\Delta/\log \Delta)$ colors. His proof, which uses the nibble method and the Lovász Local Lemma, can be made algorithmic using the constructive proof of [42]. For general graphs with maximum degree $\Delta$, the interesting region is $k = \Delta - O(\sqrt{\Delta})$, since Molloy and Reed [39] showed, for sufficiently large constant $\Delta$, a polynomial-time algorithm to determine if a graph with maximum degree $\Delta$ is $k$-colorable when $k \geq \Delta - \sqrt{\Delta} + 3$. We note that most parts of the proof extend to the odd $k$ case as well, modulo the missing piece in the phase diagram.

Here is the formal statement of our inapproximability result for colorings.

**Theorem 11.** For all even $k \geq 3$, all $\Delta \geq 3$, for the $k$-colorings problem, when $k < \Delta$, unless $\text{NP}=\text{RP}$, there is no FPRAS that approximates the partition function for triangle-free $\Delta$-regular graphs. Moreover, there exists $\varepsilon = \varepsilon(k, \Delta)$ such that, unless $\text{NP}=\text{RP}$, one cannot approximate the partition function within a factor $2^{\varepsilon n}$ for triangle-free $\Delta$-regular graphs (where $n$ is the number of vertices).

Our result also extends to the anti-ferromagnetic Potts model. As we mentioned earlier, somewhat surprisingly, the uniqueness/non-uniqueness threshold for the infinite tree $T_\Delta$ is not known for the antiferromagnetic Potts model. We prove that the uniqueness/non-uniqueness threshold for semi-translation invariant Gibbs measures on $T_\Delta$ occurs at $B_c(\Delta) = \Delta - q/\Delta$. We believe this threshold coincides with the uniqueness/non-uniqueness threshold, unlike in the case of colorings. We prove, for even $q$, that approximating the partition function is NP-hard in the non-uniqueness region for semi-translation invariant measures.

**Theorem 12.** For all even $q \geq 3$, all $\Delta \geq 3$, for the antiferromagnetic $q$-state Potts model, for all $B < \Delta - q/\Delta$, unless $\text{NP}=\text{RP}$, there is no FPRAS that approximates the partition function for triangle-free $\Delta$-regular graphs. Moreover, there exists $\varepsilon = \varepsilon(q, \Delta)$ such that, unless $\text{NP}=\text{RP}$, one cannot approximate the partition function within a factor $2^{\varepsilon n}$ for triangle-free $\Delta$-regular graphs (where $n$ is the number of vertices).

In fact, we obtain inapproximability of the partition function for any antiferromagnetic
model when there is non-uniqueness of semi-translation invariant measures on $\mathbb{T}_\Delta$ and mild additional conditions. Our results for general models are stated in Section 1.4.4.

### 1.4.3.1 Dominant Phases for Antiferromagnetic Potts and Colorings Models

To obtain Theorems 11 and 12, we need to figure out the dominant phases in a random bipartite regular graph for the antiferromagnetic Potts and colorings models. Recall, the interaction matrix $B$ for the Potts model is completely determined by a parameter $B$. The antiferromagnetic regime corresponds to $0 < B < 1$. The coloring model is the zero temperature limit of the Potts model and corresponds to the particular case $B = 0$ in what follows. We should note that in statistical physics terms, the arguments of this section are closely related to the phase diagrams of the models.

Recall that the critical points of $\Psi_1$ are given by fixpoints of the tree recursions. For the Potts model, the tree recursions (7) can be written as:

$$
R_i \propto \left( BC_i + \sum_{j \neq i} C_j \right)^{\Delta^{-1}}, \quad C_j \propto \left( BR_j + \sum_{i \neq j} R_i \right)^{\Delta^{-1}}, \quad (17)
$$

Using Theorem 2 to connect Jacobian attractive fixpoints and dominant phases together with the function $\Phi$ of Theorem 5, we establish the following theorem in Section 6.3.

**Theorem 13.** Let $0 \leq B < 1$ and $\Delta \geq 3$.

1. When $q \geq \Delta + 1$ or $B \geq \frac{\Delta-q}{\Delta}$, there is a unique fixpoint of (17) which is translation invariant. Thus the model is in the semi-translation invariant uniqueness regime of $\mathbb{T}_\Delta$.

2. When $q < \Delta$ and $0 \leq B < \frac{\Delta-q}{\Delta}$, there are multiple fixpoints of (17). Thus the model is in the semi-translation invariant non-uniqueness regime of $\mathbb{T}_\Delta$.

3. For all even $q \geq 3$, for all $\Delta \geq 3$, when $q < \Delta$ and $0 \leq B < \frac{\Delta-q}{\Delta}$, the dominant phases $(\alpha, \beta)$ are in one-to-one correspondence with subsets $T \subseteq [q]$ with $|T| = q/2$. Moreover, there exist $a, b$ such that for $T \subseteq [q]$ with $|T| = q/2$, the dominant phase
\((\alpha, \beta)\) corresponding to \(T\) satisfies

\[
\alpha_i = a \text{ if } i \in T, \quad \alpha_i = b \text{ if } i \notin T, \\
\beta_i = b \text{ if } i \in T, \quad \beta_i = a \text{ if } i \notin T.
\]

1.4.3.2 The Gadget and Its Properties

In this section, we give the main elements of our inapproximability results. We start by reviewing the main components of the reduction for 2-spin systems (as carried out in [49, 50]) and in particular the hard-core model. This will allow us to isolate the parts of the argument which do not extend to the multi-spin case and motivate our reduction scheme.

To simplify the presentation, we shall focus on the colorings model \((k \text{ even})\), but the same ideas can be generalized to the Potts model and (with more technical effort) to arbitrary antiferromagnetic multi-spin models.

The basic gadget in the reduction is a bipartite random graph, which we denote by \(G\). The sides of the bipartition have an equal number of vertices, and the sides are labelled with + and −. Most vertices in \(G\) have degree \(\Delta\) but there is also a small number of degree \(\Delta - 1\) vertices (to allow to make connections between gadgets without creating degree \(\Delta + 1\) vertices). For \(s = \{+, -\}\), let the vertices in the \(s\)-side be \(U^s \cup W^s\) where the vertices in \(U = U^+ \cup U^-\) have degree \(\Delta\) and the vertices in \(W = W^+ \cup W^-\) have degree \(\Delta - 1\). The phase of an independent set \(I\) is + (resp. −) if \(I\) has more vertices in \(U^+\) (resp. \(U^-\)). Note that the phase depends only on the spins of the “large” portion of the graph, i.e., the spins of vertices in \(U\).

In non-uniqueness regimes, the gadget \(G\) has two important properties, both of which can be obtained by building on the second moment argument we outlined earlier. First, the phase of a random independent set \(I\) is equal to + or − with probability roughly equal to 1/2. Second, conditioned on the phase of a random independent set \(I\), the spins of the vertices in \(W\) are approximately independent, i.e., the marginal distribution on \(W\) is close to a product distribution. In this product distribution if the phase is + (resp. −), a vertex in \(W^+\) is in \(I\) with probability \(p^+\) (resp. \(p^-\)), while a vertex in \(W^-\) is in \(I\) with probability \(p^-\) (resp. \(p^+\)). The values \(p^\pm\) correspond to maxima of the function \(\Psi_1\) and, crucially (as
we shall demonstrate shortly), they satisfy $p^+ \neq p^-$. 

Using the second moment analysis and in particular Theorem 4, we can prove that an analogous phenomenon takes place for the $k$-colorings model in the semi-translation non-uniqueness regime. The main difference is that, instead of two phases, the number of phases is equal to the number of maximizers of the function $\Psi_1$, cf. Theorem 13. For $k$ even, the phase of a coloring is determined by the dominant set of $k/2$ colors on $U^+$, i.e., the $k/2$ colors with largest frequencies among vertices of $U^+$. Each of the $\binom{k}{k/2}$ phases appears with roughly equal probability and given the phase, the marginal distribution on $W$ is close to a product distribution, which we now describe. We can compute explicit values $a = a(k, \Delta), b = b(k, \Delta)$ such that for a phase $T \in \binom{k}{k/2}$ the probability mass function $x$ of a vertex in $W^+$ has its $i$-th entry equal to $a$ if $i \in T$ and equal to $b$ if $i \notin T$. Similarly, the probability mass function $y$ of a vertex in $W^-$ has its $i$-th entry equal to $b$ if $i \in T$ and equal to $a$ if $i \notin T$. We note here that the values of $a, b$ can be determined using the mapping between the dominant phases (described in Theorem 13) and their respective fixpoints of the tree recursions (see (11)); see also Section 6.3 for a cleaner picture.

Let $Q$ be the union of the pairs $(x, y)$ over all phases. Hereafter, we will identify the phases with elements of $Q$. Note that if $(x, y) \in Q$, then $(y, x) \in Q$ as well. We also denote by $Q'$ the union of unordered elements of $Q$. Elements of $Q'$ are called unordered phases (we use $p$ to denote unordered phases). Given a phase $p = \{x, y\}$ an ordering of the pair will be called “assigning spin to the phase”. The two ordered phases corresponding to the unordered phase $p$ will be denoted by $p^+$ and $p^-$. 

The conditional independence property is crucial. It allows to quantify the effect of using vertices of $W$ as terminals to make connections between copies of the gadget $G$. For example, consider the following type of connection, which we refer to as parallel. Let $v^+ \in W^+, \ v^- \in W^-$ and consider two copies of the gadget $G$, say $G_1, G_2$. For $i = 1, 2$ denote by $v_i^+, v_i^-$ the images of $v^+, v^-$ in $G_i$. Now add the edges $(v_1^+, v_2^+)$ and $(v_1^-, v_2^-)$ and denote the final graph by $G_{12}$. Thus, a parallel connection corresponds to joining the $+, +$ and $-, -$ sides of two copies of the gadget.

Clearly, random colorings of $G_{12}$ can be generated by first generating random colorings
of $G_1, G_2$ and keeping the resulting coloring if $v_1^+, v_2^+$ have different colors. We thus have that the partition function of $G_{12}$ is equal to $(Z_G)^2$ times the probability that $v_1^+, v_2^+$ have different colors in random colorings of $G_1, G_2$. The latter quantity can easily be computed if we condition on the phases $(x_1, y_1), (x_2, y_2)$ of the colorings in $G_1, G_2$, and this is equal to $(1 - x_1^T x_2)(1 - y_1^T y_2)$.

By taking logarithms, we can assume a parallel connection between gadgets with phases $(x_1, y_1)$ and $(x_2, y_2)$ incurs an (additive) weight

$$w_p((x_1, y_1), (x_2, y_2)) = \ln(1 - x_1^T x_2) + \ln(1 - y_1^T y_2).$$

In the hard-core model, parallel connections are sufficient to give hardness. In this case, we have that $Q' = \{p\}$ and $Q = \{p^+, p^-\}$ and the respective function $w_p(\cdot, \cdot)$ satisfies

$$w_p(p^+, p^-) = w_p(p^-, p^-) < w_p(p^+, p^-).$$

Thus, in this case, $w_p(\cdot, \cdot)$ takes only two values and neighboring gadgets prefer to have different phases. Now assume that $H$ is an instance of MAX-CUT and replace each vertex in $H$ by a copy of the gadget $G$, while for each edge of $H$, connect the respective gadgets in parallel. The partition function of the final graph is dominated from phase assignments which correspond to large cuts in $H$. This intuition is the basis of the reduction in [49, 50].

For the colorings model, reducing from MAX-CUT poses an extra challenge. While for every unordered phase $p$ equation (18) continues to hold, a short calculation shows that the optimal configuration for a triangle of gadgets connected in parallel is to give all three gadgets different phases. To bypass this entanglement, we need to introduce some sort of ferromagnetism in the reduction to enforce gadgets corresponding to vertices of $H$ to use a single (unordered) phase. To achieve this, we use symmetric connections, which correspond to having not only $(+, +), (-, -)$ connections of the gadgets, but also $(+, -)$ and $(-, +)$. Thus, a symmetric connection whose endpoints have phases $(x_1, y_1), (x_2, y_2)$ incurs (additive) weight

$$w_s((x_1, y_1), (x_2, y_2)) = w_p((x_1, y_1), (x_2, y_2)) + w_p((x_1, y_1), (y_2, x_2)).$$
Symmetric connections will allow us to enforce a single unordered phase to all gadgets, while parallel connections will allow us to recover a maximum-cut partition. To have some modularity in our construction, rather than reducing from Max-Cut directly, we use the following “phase labeling problem”.

**Colorings Phase Labeling Problem** ($\mathcal{Q}$):

**INPUT**: undirected edge-weighted multigraph $H = (V, E)$ and a partition of the edges $\{E_p, E_s\}$.

**OUTPUT**: $\text{MAXLWT}(H) := \max_{\mathcal{Y}} \text{LWT}_H(\mathcal{Y})$, where the maximization is over all possible phase labelings $\mathcal{Y} : V \to \mathcal{Q}$ and

$$\text{LWT}_H(\mathcal{Y}) := \sum_{\{u,v\} \in E_s} w_s(\mathcal{Y}(u), \mathcal{Y}(v)) + \sum_{\{u,v\} \in E_p} w_p(\mathcal{Y}(u), \mathcal{Y}(v)).$$

Edges in $E_p$ (resp. $E_s$) correspond to parallel (resp. symmetric) connections and we shall refer to them as parallel (resp. symmetric) edges. The arguments in [50], which we sketched earlier, can easily be adapted to show that an algorithm for approximating the partition function to an arbitrarily small exponential factor yields a PRAS for the phase labeling problem, see Lemma 55 in Section 5.2. The harder part of our arguments is to show that a PRAS for the phase labeling problem yields a PRAS for Max-Cut on 3-regular graphs, see Lemma 56 and its proof in Section 5.3.1.

### 1.4.4 Inapproximability for General Antiferromagnetic Models

The inapproximability results for colorings can be extended to general antiferromagnetic models on bounded degree graphs. The key concept in the general theorem is again the existence of long range correlations, in the form of semi-translation non-uniqueness on the infinite regular tree.

We use the following definition of antiferromagnetic models, which is in terms of the signature of the interaction matrix $\mathbf{B}$, i.e., the signs of its eigenvalues. Recall that the interaction matrix $\mathbf{B}$ is symmetric and hence its eigenvalues are real. Moreover, it is simple to see that the matrices $\mathbf{B}$ which correspond to non-degenerate models should be irreducible. The Perron-Frobenius theorem then implies that one of the eigenvalues with the largest magnitude is positive. When all the other eigenvalues are negative, we show in Section 5.1
(see Corollary 53) that neighboring spins prefer to be different and hence we call such models antiferromagnetic. This notion of antiferromagnetism extends naturally the definition for 2-spin models (see [21, 33, 50]) and also captures antiferromagnetism in the Potts model. A more thorough discussion is given in Section 5.1.

Proceeding to the general hardness results, we have already displayed that the second moment argument for random bipartite graphs covers arbitrary models (general interaction matrix $B$). There are two properties of the gadget $G$ in Section 1.4.3.2 we need to ensure. First, the symmetry breaking between the two sides of the graph, i.e., a typical configuration should have different color frequencies on the two sides of the graph. Second, to be able to quantify the interaction between neighboring gadgets, we need to ensure that phases appear with roughly equal probability and that given the phase, the spins of the vertices with degree $\Delta - 1$ are approximately independent.

The first property can be guaranteed by the absence of translation invariant phases, i.e., maximizers of the function $\Psi_1$ of the form $(x, x)$. Since in uniqueness regimes the only maximizer is translation invariant, this can be the case only in non-uniqueness regimes. The second property is subtler and relates to the concentration properties of the random variable $Z_{G}^{\alpha, \beta}$. The required concentration is sufficiently strong when the maximizers $\alpha, \beta$ (viewed as unordered pairs) of the function $\Psi_1$ are (i) Hessian maxima, i.e., the Hessian matrix of $\Psi_1$ is negative definite when evaluated at $(\alpha, \beta)$, and (ii) permutation symmetric, i.e., obtainable from one another by a suitable permutation of the set of spins (equivalently, the coordinates of $\alpha_i$’s and $\beta_j$’s). We clarify that the permutations must be automorphisms of the interaction matrix $B$. For example, note that the maxima for the colorings model are permutation symmetric.

Given these assumptions, the proof approach in Section 1.4.3.2 (with some extra work) can be adapted to give the following general inapproximability result.

**Theorem 14.** Let $q \geq 2, \Delta \geq 3$. For an antiferromagnetic $q$-spin system with interaction matrix $B$, if the dominant semi-translation invariant Gibbs measures on the tree $\mathbb{T}_{\Delta}$ are permutation symmetric and all of them are Hessian dominant and not translation invariant
then, unless $NP=RP$, there is no FPRAS for approximating the partition function for triangle free $\Delta$-regular graphs. Moreover, there exists $\varepsilon = \varepsilon(q, \Delta)$ such that, unless $NP=RP$, one cannot approximate the partition function within a factor $2^{\varepsilon n}$ for triangle-free $\Delta$-regular graphs (where $n$ is the number of vertices).

In fact Theorems 11 and 12 can be obtained as corollaries of Theorem 14 after using the phase diagram given in Theorem 13. We also do the analogous much easier task for antiferromagnetic 2-spin systems in Section 6.1 and thus obtain Theorem 10.

1.4.5 AP-reductions for Graphs of Bounded Degree

The sharp transition in the complexity of the hard-core model on graphs with maximum degree $\Delta$ is one of the most striking computational dichotomies. It would be interesting thus to explore deeper the boundaries of this dichotomy.

A natural such question is whether the same computational transition remains true for bipartite graphs of maximum degree $\Delta$. One side is trivial: in the regime $\lambda < \lambda_c(\mathbb{T}_\Delta)$, Weitz’s algorithm applies invariably irrespectively of the underlying graph structure (provided of course that the maximum degree is $\Delta$). On the hardness side, the things are no longer clear. Even for general bipartite graphs (with unbounded degree) a strong NP-hardness result is considered unlikely, though it is conjectured to not admit an FPRAS. The class of problems whose approximation complexity is equivalent to counting independent sets on bipartite graphs (which we will abbreviate as #BIS) includes many natural problems, see for example [14].

Most #BIS-hardness results have thus far focused on graphs without degree bounds. We make a step for bipartite graphs of bounded degree, first in the case of the hard-core model, proving #BIS-hardness for the hard-core model throughout the non-uniqueness regime of $\mathbb{T}_\Delta$. Thus, if the conjectured hardness of #BIS holds true, the following Theorem 15 is tight.

**Theorem 15.** For all $\Delta \geq 3$, for the hard-core model, for any $\lambda > \lambda_c(\mathbb{T}_\Delta)$, it is #BIS-hard to obtain an FPRAS that approximates the partition function for bipartite graphs of maximum degree $\Delta$. 

39
We prove an analogous result for the ferromagnetic Potts model. We utilize an important result of Goldberg and Jerrum [20], who showed that approximating the partition function of the ferromagnetic Potts model on general graphs is BIS-hard. Our result shows that the hardness is maintained if one restricts to bounded degree bipartite graphs, provided the temperature $B$ is bigger than a natural threshold $\mathcal{B}_o$ (a function of $q, \Delta$), see Section 6.2.

**Theorem 16.** For all $q \geq 3$, all $\Delta \geq 3$, for the ferromagnetic $q$-state Potts model, for any $B > \mathcal{B}_o$, it is BIS-hard to obtain an FPRAS that approximates the partition function for graphs of maximum degree $\Delta$.

The threshold $\mathcal{B}_o$, rather than being the uniqueness threshold of the ferromagnetic Potts model, is the *phase coexistence point* on a random $\Delta$-regular graph (whose existence we establish). When $B < \mathcal{B}_o$, the uniform vector is the only dominant phase; when $B > \mathcal{B}_o$, the uniform vector over the spins is not a dominant phase and $q$ permutation symmetric dominant phases exist; at $B = \mathcal{B}_o$, the model has $q+1$ dominant phases, the uniform vector and the $q$ permutation symmetric dominant phases. For more details, see Theorem 64 in Section 6.2.
CHAPTER II

SPIN MODELS ON RANDOM REGULAR BIPARTITE GRAPHS

Random regular bipartite graphs will serve as building blocks for the gadgets we use in our hardness reductions. Thus, a major component in this thesis is the analysis of spin systems on models of random regular graphs. Our primary focus will be on random bipartite $\Delta$-regular graphs; this graph distribution is formally defined in Section 2.1.1. Extensions to random regular graphs are discussed in Chapter 8.

To obtain results for the Gibbs distribution which hold with high probability over the choice of the graph, we shall employ a second moment approach based on the small subgraph conditioning method. We formulate the main technical aspects of the moment approach in Section 2.2.1 and review the small subgraph conditioning method in Section 2.3, all in the spin model setting. Later chapters will progressively establish and refine the various components needed in the analysis.

The reader who is acquainted with similar settings as ours will effectively recognize a good portion of the notions and methods, modulo perhaps the specific technical details. Namely, both the use of moments and the small subgraph conditioning method are well established techniques which have been applied to numerous problems in probabilistic combinatorics and statistical physics. Despite this, the technical details change substantially for each instantiation of the method and the purpose of this chapter is to set up a concrete basis for our later investigations.

2.1 Preliminaries

2.1.1 The distribution on $\Delta$-regular Bipartite Graphs

We will use the following simple variant of the standard pairing model (also known as the configuration model [2, 5]) to study random $\Delta$-regular bipartite graphs.

Let $V_1, V_2$ be disjoint sets of vertices with $|V_1| = |V_2| = n$. For an integer $\Delta \geq 3$, we will denote by $\mathcal{G}_{n,\Delta}$ the graph distribution on the set of bipartite $\Delta$-regular multigraphs
generated by the following random process. First, sample uniformly at random $\Delta$ perfect matchings between $V_1$ and $V_2$. Then, construct a graph $G$ with vertex set $V_1 \cup V_2$ whose edges are given by the union of the $\Delta$ perfect matchings. $G$ is simple if it does not contain parallel edges.

For the sake of completeness, we next compare the distribution $\mathcal{G}_{n,\Delta}$ with the standard pairing model $\mathcal{P}_{n,\Delta}$ for random $\Delta$-regular bipartite graphs. The conclusion we are going to make is that there is no loss in working with the distribution $\mathcal{G}_{n,\Delta}$. The reader may skip the remainder of the paragraph without impact on what follows. $\mathcal{P}_{n,\Delta}$ is generated by a uniformly random perfect matching between $[V_1] \times [\Delta]$ and $[V_2] \times [\Delta]$ and then naturally projecting the edges of the matching on $V_1 \times V_2$. Let $G \sim \mathcal{P}_{n,\Delta}$ and let $\mathcal{P}_{n,\Delta}^s$ be the conditional distribution on $G$ being simple. It is easy to see that $\mathcal{P}_{n,\Delta}^s$ is the uniform distribution over the set of labelled $\Delta$-regular bicoloured graphs. It is well known that the distributions $\mathcal{P}_{n,\Delta}$ and $\mathcal{P}_{n,\Delta}^s$ are contiguous; a property holds asymptotically almost surely\(^1\) over the distribution $\mathcal{G}_{n,\Delta}$ iff it holds asymptotically almost surely over the distribution $\mathcal{P}_{n,\Delta}^s$ (see [26, Section 9.6] for a formal account of contiguity). It has been proved in [25, 41] that $\mathcal{G}_{n,\Delta}$ is contiguous to $\mathcal{P}_{n,\Delta}$ and hence to $\mathcal{P}_{n,\Delta}^s$.

### 2.1.2 Spin Systems

For an integer $q \geq 2$, a $q$-spin system is specified by a symmetric $q \times q$ interaction matrix $\mathbf{B} = (B_{ij})_{i,j \in [q]}$ with non-negative entries, which specify the strength of the interaction between the spins.

For a finite undirected graph $G = (V, E)$, a $q$-spin system is a probability distribution $\mu_G$ over the space $\Omega_G$ of all configurations, i.e., spin assignments $\sigma : V \rightarrow [q]$. The weight of a configuration $\sigma \in \Omega_G$ is the product of neighboring spin interactions, that is,

$$w_G(\sigma) = \prod_{(u,v) \in E} B_{\sigma(u)\sigma(v)}.$$

The distribution $\mu_G$, known as the Gibbs distribution is defined as $\mu_G(\sigma) = w_G(\sigma)/Z_G$.

\(^1\)Formally, a property can be interpreted as a sequence of events $A_n$ in underlying probability spaces $(\Omega_n, \mathcal{A}_n, P_n)$. Then, a property holds asymptotically almost surely if $P_n(A_n) \rightarrow 1$ as $n \rightarrow \infty$. We will abbreviate asymptotically almost surely by a.a.s.
where $Z_G$ is the partition function defined as $Z_G = \sum_{\sigma \in \Omega_G} w_G(\sigma)$. We drop the subscript $G$ when the graph under consideration is clear.

### 2.2 A moments’ approach for spin models on random graphs

#### 2.2.1 Expressions for the first and second moments

Let $G \sim G_{n,\Delta}$ where $G_{n,\Delta}$ was defined in Section 2.1.1. Briefly, $G_{n,\Delta}$ is the probability distribution over bipartite graphs with $n + n$ vertices formed by taking the union of $\Delta$ random perfect matchings. We will denote the two sides of the bipartition of the graphs as $V_1, V_2$.

For a $q$-spin system with interaction matrix $B$, we will study the Gibbs distribution of the random graph $G$ using the moments of the partition function. We first set up our notation.

We denote by $\Delta_t$ the simplex of $t$-dimensional probability vectors, i.e.,

$$\Delta_t := \{(x_1, x_2, \ldots, x_t) \in \mathbb{R}^t \mid \sum_{i=1}^t x_i = 1 \text{ and } x_i \geq 0 \text{ for } i = 1, \ldots, t\}.$$  \hspace{1cm} (19)

For a configuration $\sigma : V_1 \cup V_2 \rightarrow \{1, \ldots, q\}$, we shall denote the set of vertices assigned color $i$ by $\sigma^{-1}(i)$. For $\alpha, \beta \in \Delta_q$, let

$$\Sigma^{\alpha,\beta} := \{\sigma : V \rightarrow \{1, \ldots, q\} \mid |\sigma^{-1}(i) \cap V_1| = \alpha_i n, |\sigma^{-1}(i) \cap V_2| = \beta_i n \text{ for } i = 1, \ldots, q\},$$  \hspace{1cm} (20)

that is, configurations in $\Sigma^{\alpha,\beta}$ assign $\alpha_i n$ and $\beta_i n$ vertices in $V_1$ and $V_2$ the spin value $i$, respectively. We will be interested in the total weight $Z_G^{\alpha,\beta}$ of configurations in $\Sigma^{\alpha,\beta}$, namely

$$Z_G^{\alpha,\beta} = \sum_{\sigma \in \Sigma^{\alpha,\beta}} w_G(\sigma).$$

Thus, the random variable $Z_G^{\alpha,\beta}$ can be interpreted as a conditional partition function on those configurations with vertex empirical distribution given by $\alpha, \beta$. Note that the partition function $Z_G$ is the sum of $Z_G^{\alpha,\beta}$, over the set of all possible $\alpha, \beta \in \Delta_q$.

We will study $Z_G^{\alpha,\beta}$ by looking at the moments $E_G[Z_G^{\alpha,\beta}]$ and $E_G[(Z_G^{\alpha,\beta})^2]$. We begin with the first moment. Let $\alpha, \beta \in \Delta_q$. For $\sigma \in \Sigma^{\alpha,\beta}$ and a matching between $V_1$ and $V_2$, let $nx_{ij}$ denote the number of edges matching vertices in $\sigma^{-1}(i) \cap V_1$
and $\sigma^{-1}(j) \cap V_2$ and set $x := (x_{11}, \ldots, x_{qq})$. Note that $x$ is itself a probability vector in $\triangle_{q^2}$, capturing the edge empirical distribution under the configuration $\sigma$. In particular, $x$ must have the right marginals on the sets $V_1, V_2$. Precisely, $x \in M_1(\alpha, \beta)$, where $M_1(\alpha, \beta)$ is the polytope

$$
M_1(\alpha, \beta) := \left\{ x : \begin{array}{l}
\sum_j x_{ij} = \alpha_i \ (\forall i \in [q]), \\
\sum_i x_{ij} = \beta_j \ (\forall j \in [q]), \\
x_{ij} \geq 0 \ (\forall (i, j) \in [q]^2) \end{array} \right\}.
$$

(21)

To make the following expressions more compact, for $i, j \in [q]$, we denote

$$
x_{i[q]} := (x_{i1}, \ldots, x_{iq}), \quad x_{[ij]} := (x_{1j}, \ldots, x_{qj}).
$$

We will also use the following notation for multinomial coefficients. For $z \in \mathbb{R}_+^q$,

$$
\binom{zn}{zn} := \left( \binom{z_1n}{1n}, \ldots, \binom{z_tn}{tn} \right)
$$

provided that $z_1 + \ldots + z_t = z$.

Under the convention that $0^0 \equiv 1$, we then have

$$
E_G[Z_G^{\alpha,\beta}] = \binom{n}{\alpha n} \binom{n}{\beta n} \left( \sum_x \left[ \binom{n}{\alpha n} \right]^{-1} \prod_i \binom{x_{i[q]}n}{\alpha_i n} \prod_j \binom{x_{[ij]}n}{\beta_j n} \right) \prod_{i,j} B_{ij}^{x_{ij}} \Delta
$$

(22)

where the sum ranges over $x \in M_1(\alpha, \beta)^2$. Let us briefly explain the derivation of (22). The term $\binom{n}{\alpha n} \binom{n}{\beta n}$ accounts for the cardinality of $\Sigma^{\alpha,\beta}$, while the remainder of the expression is $E_G[w_G(\sigma)]$ for an arbitrary $\sigma \in \Sigma^{\alpha,\beta}$. Since the weight of a configuration is multiplicative over the edges and the matchings are independent, $E_G[w_G(\sigma)]$ is the $\Delta$-power of the expected contribution of a single matching. The latter is completely determined by $x$ and is equal to $\prod_{i,j} B_{ij}^{x_{ij}}$, scaled by the probability that the matching induces the prescribed $x$, i.e.,

$$
\left[ \binom{n}{x_{i[q]}n} \right]^{-1} \prod_j \left( \binom{x_{[ij]}n}{\beta_j n} \right).
$$

The second moment $E_G[(Z_G^{\alpha,\beta})^2]$ is completely analogous, once we introduce the right variables. It will be useful though for our later investigations to study the slightly more general $E_G[Z_G^{\alpha_1,\beta_1, \alpha_2,\beta_2}]$. To do this, for $(\sigma_1, \sigma_2) \in \Sigma^{\alpha_1,\beta_1} \times \Sigma^{\alpha_2,\beta_2}$, we need to compute $E_G[w_G(\sigma_1)w_G(\sigma_2)]$. Let

$$
\gamma_{ik} = |\sigma_1^{-1}(i) \cap \sigma_2^{-1}(k) \cap V_1|/n, \quad \delta_{jl} = |\sigma_1^{-1}(j) \cap \sigma_2^{-1}(l) \cap V_2|/n.
$$

Formally, one should demand $x \in M_1(\alpha, \beta) \cap (\triangle_{2q^2})$, but in the limit $n \to \infty$ this will not affect our considerations. We suppress from the exposition such integrality considerations, which are in any case irrelevant.
The vectors $\gamma := (\gamma_{11}, \ldots, \gamma_{qq})$ and $\delta = (\delta_{11}, \ldots, \delta_{qq})$ capture the overlap of configurations in $V_1$ and $V_2$, respectively. In particular, observe that $\gamma$ and $\delta$ satisfy the marginal constraints

$$\gamma \in \mathcal{M}_1(\alpha_1, \alpha_2), \delta \in \mathcal{M}_1(\beta_1, \beta_2),$$

where the polytope $\mathcal{M}_1(\cdot, \cdot)$ is given by (21). To capture $w_G(\sigma_1)w_G(\sigma_2)$, for a matching between $V_1$ and $V_2$, let $n_{y_{ikjl}}$ denote the number of edges matching vertices in $\sigma_1^{-1}(i) \cap \sigma_2^{-1}(k) \cap V_1$ and $\sigma_1^{-1}(j) \cap \sigma_2^{-1}(l) \cap V_2$. The vector $y = (y_{1111}, \ldots, y_{qqqq})$ must lie in the polytope $\mathcal{M}_2(\gamma, \delta)$, where

$$\mathcal{M}_2(\gamma, \delta) := \left\{ y : \sum_{i,j,l} y_{ikjl} = \gamma_{ik} \ (\forall (i,k) \in [q]^2), \sum_{i,k} y_{ikjl} = \delta_{jl} \ (\forall (j,l) \in [q]^2), \right\}$$

$$y_{ikjl} \geq 0 \ (\forall (i,k,j,l) \in [q]^4).$$

Again, to make the expressions compact, for $i, k, j, l \in [q]$, we denote

$$y_{ik[q]} := (y_{ik11}, \ldots, y_{ikqq}), \quad y_{[q]jl} := (y_{11jl}, \ldots, y_{qqjl}).$$

Under the convention $0^0 \equiv 1$, we then have

$$E_G[Z_G^{\alpha_1, \beta_1}Z_G^{\alpha_2, \beta_2}] =$$

$$\sum_{\gamma, \delta} \left( \begin{matrix} n \\ \gamma \end{matrix} \right) \left( \begin{matrix} n \\ \delta \end{matrix} \right) \left( \sum_{y} \left[ \left( \begin{matrix} n \\ \gamma \end{matrix} \right)^{-1} \prod_{i,k} \left( \gamma_{ik} y_{ik[q]} \right) \prod_{j,l} \left( \delta_{jl} y_{[q]jl} \right) \right] \prod_{ikjl} (B_{ij}B_{kl})^{n_{y_{ikjl}}} \right)^\Delta,$$

where the sums range over $\gamma \in \mathcal{M}_1(\alpha_1, \alpha_2), \delta \in \mathcal{M}_1(\beta_1, \beta_2), y \in \mathcal{M}_2(\gamma, \delta)$. The first line in (24) accounts for the cardinality of $\Sigma^{\alpha_1, \beta_1} \times \Sigma^{\alpha_2, \beta_2}$, while the second line is $E_G[w_G(\sigma_1)w_G(\sigma_2)]$ for $(\sigma_1, \sigma_2) \in \Sigma^{\alpha_1, \beta_1} \times \Sigma^{\alpha_2, \beta_2}$ with the prescribed $\gamma, \delta$. Since the weight of a configuration is multiplicative over the edges and the matchings are independent, $E_G[w_G(\sigma_1)w_G(\sigma_2)]$ is the $\Delta$-power of the expected weight of a single matching. The latter is completely determined by $y$ and is equal to $\prod_{i,k,j,l} (B_{ij}B_{kl})^{y_{ikjl}}$, scaled by the probability that the matching induces the prescribed $y$.

By restricting to the case $\alpha_1 = \alpha_2 = \alpha, \beta_1 = \beta_2 = \beta$ we obtain $E_G[(Z_G^{\alpha, \beta})^2]$. Note that only the range of the sums in (24) change (the regions that $\gamma, \delta$ are allowed to lie); other than that, the expressions are identical. In fact, we have the following simple remark.
Remark 2. The second moment of the partition function of \( G \) is given by (24), where the sum ranges over all \( \gamma, \delta \in \triangle_{q^2} \). More generally (and precisely), for \( \Sigma \subseteq \triangle_q \times \triangle_q \), denote by

\[
Z_G(\Sigma) = \sum_{(\alpha, \beta) \in \Sigma} Z_{G, \alpha, \beta}^G,
\]

so that \( (Z_G(\Sigma))^2 = \sum_{(\alpha_1, \beta_1), (\alpha_2, \beta_2) \in \Sigma} Z_{G, \alpha_1, \beta_1}^G Z_{G, \alpha_2, \beta_2}^G \)

The second moment \( E_G[(Z_G(\Sigma))^2] \) is given by (24), where now the first sum ranges over all

\[
(\gamma, \delta) \in \bigcup_{(\alpha_1, \beta_1), (\alpha_2, \beta_2) \in \Sigma} M_1(\alpha_1, \alpha_2) \times M_1(\beta_1, \beta_2).
\]

The following equally simple remark will be much more crucial:

Remark 3. The second moment can be interpreted as the first moment of a paired-spin model with interaction matrix \( B \otimes B \). Indeed, we can interpret \( B_{ij} B_{kl} \) as the edge activity between the paired spins \((i, k)\) and \((j, l)\), thus giving the desired alignment.

2.2.2 The Exponential Order of the Moments

In this section, we study the limits of \( \frac{1}{n} \log E_G[Z_G^{\alpha, \beta}] \) and \( \frac{1}{n} \log E_G[(Z_G^{\alpha, \beta})^2] \) as \( n \to \infty \). These limits exist under relatively mild conditions as we discuss below (see Remark 4).

Roughly, the calculation of these limits involves expanding the factorials using Stirling’s approximation and finding the maximum of the resulting function. The intuition here is that the terms in the sums (22) and (24) are typically exponential in \( n \), but have polynomially many terms. This gives that their asymptotic order is determined by a few terms close to their dominating terms.

Under the usual conventions that \( \ln 0 \equiv -\infty \) and \( 0 \ln 0 \equiv 0 \), we obtain the following:

\[
\Psi_1(\alpha, \beta) := \lim_{n \to \infty} \frac{1}{n} \log E_G[Z_G^{\alpha, \beta}] = \max_{x \in M_1(\alpha, \beta)} \Upsilon_1(\alpha, \beta, x),
\]

where

\[
\Upsilon_1(\alpha, \beta, x) := (\Delta - 1) f_1(\alpha, \beta) + \Delta g_1(x)
\]

\[
f_1(\alpha, \beta) := \sum_i \alpha_i \ln \alpha_i + \sum_j \beta_j \ln \beta_j
\]

\[
g_1(x) := \sum_{i,j} x_{ij} \ln B_{ij} - \sum_{i,j} x_{ij} \ln x_{ij}.
\]
And for the second moment:

$$
\Psi_2(\alpha, \beta) := \lim_{n \to \infty} \frac{1}{n} \log \mathbb{E}_G[(Z_G^{\alpha,\beta})^2] = \max_{\gamma \in M_1(\alpha, \beta)} \max_{\delta \in M_1(\beta, \beta)} \Upsilon_2(\gamma, \delta, y),
$$

where $$\Upsilon_2(\gamma, \delta, y) := (\Delta - 1)f_2(\gamma, \delta) + \Delta g_2(y)$$

$$
f_2(\gamma, \delta) := \sum_{i,k} \gamma_{ik} \ln \gamma_{ik} + \sum_{j,l} \delta_{jl} \ln \delta_{jl}
$$

$$
g_2(y) := \sum_{i,k,j,l} y_{ikjl} \ln(B_{ij}B_{kl}) - \sum_{i,k,j,l} y_{ikjl} \ln y_{ikjl}
$$

**Remark 4.** We expand at a lower level of technical detail our discussion on the existence of the limits $$\frac{1}{n} \log \mathbb{E}_G[Z_G^{\alpha,\beta}]$$ and $$\frac{1}{n} \log \mathbb{E}_G[(Z_G^{\alpha,\beta})^2]$$. Assuming that the Hessian of these functions is negative definite at the respective maxima, one can use a Gaussian integral around the maximizers to compute the asymptotics of $$\mathbb{E}_G[Z_G^{\alpha,\beta}]$$ and $$\mathbb{E}_G[(Z_G^{\alpha,\beta})^2]$$, i.e., the tails of these sums are negligible. The technique has been coined as Laplace’s method (see for example [9, Chapter 4] or [53, Chapter IX]). This is exactly what we are going to do in Chapter 4 and the reason behind the Hessian condition in Theorem 14. It should be noted however that the limits of the logarithms of the moments may be justified under much milder conditions, see for example [37]. We do not follow this path here since we will need the asymptotics of the moments.

**Remark 5.** The maximization in the first moment depends only on the function $$g_1(x)$$ which is strictly concave in the convex region over the convex polytope $$M_1(\alpha, \beta)$$. Hence, for any fixed $$\alpha, \beta$$, the global maximum of $$\Upsilon_1(\alpha, \beta, x)$$ with respect to $$x$$ is achieved at a unique point. Similarly, for any fixed $$\gamma, \delta$$, the maximum of $$\Upsilon_2(\gamma, \delta, y)$$ with respect to $$y$$ is achieved at a unique point. Crucially for our considerations in Section 4.3, if $$\alpha, \beta$$ are global maximizers of $$\Psi_1$$, the global maximum of $$\Upsilon_2(\gamma, \delta, y)$$ with respect to $$\gamma, \delta, y$$ is also achieved at a unique point, see Lemma 28 in Section 3.3.3.

A notational convention that we have adopted silently so far is perhaps useful to allude: the indices $$i, k$$ “point” to the set $$V_1$$, while indices $$j, l$$ “point” to the set $$V_2$$. 

47
2.3 Bits on the Small Subgraph Conditioning Method

The small graph conditioning method was introduced in [46] to prove that a random \( \Delta \)-regular contains asymptotically almost surely (a.a.s) a Hamilton cycle. Roughly speaking, the method provides a way to get a.a.s results when the second moment method fails, in the particular case (though common in the random regular setting) where the ratio of the second moment of a variable to the first moment squared converges to a constant strictly greater than 1.

The method was first used to analyze spin models on random regular graphs in [43] and was subsequently used in [49, 17]. In our setting, applying the small subgraph conditioning method of [46] as in the previous works [43, 49, 17] would not be sufficient, since it guarantees a polynomial multiplicative deviation from the expectation, which would be weak in the setting of the upcoming Theorem 31. We instead use in full power an extension of the method given by Janson [25].

More generally, the method of [46] is sufficient when the interest is in proving concentration of a variable within a polynomial factor from its expectation. Janson’s refinement of the method gives the distributional limit of the variable and as a corollary attributes the fluctuations from the expectation to the presence of specific subgraph structures. For the convenience of the reader, we include both versions of the method in Theorem 17, which is a concatenated version of the respective Theorems in [46, 25]. The theorem can be extrapolated from [25], after combining [25, Lemma 1, Remark 4, Remark 9]. The notation \( [X]_m \) refers to the \( m \)-th order falling factorial of the variable \( X \). We shall discuss the theorem statement afterwards.

**Theorem 17.** Let \( S \) be a set of finite cardinality. For \( s \in S \) and \( i = 1, 2, \ldots \), let \( \lambda_i > 0 \) and \( \delta_i^{(s)} > -1 \) be constants and assume that for each \( n \) there are random variables \( X_{in} \), \( i = 1, 2, \ldots \), and \( Y_n^{(s)} \), \( s \in S \), all defined on the same probability space \( \mathcal{G} = \mathcal{G}_n \) such that \( X_{in} \) is non-negative integer valued, \( Y_n^{(s)} \geq 0 \) and \( E[Y_n^{(s)}] > 0 \) (for \( n \) sufficiently large). Furthermore, for every \( s \in S \), the following hold:

(A1) \( X_{in} \overset{d}{\to} Z_i \) as \( n \to \infty \), jointly for all \( i \), where \( Z_i \sim Po(\lambda_i) \) are independent Poisson
random variables;

(A2) for every finite sequence $j_1, \ldots, j_m$ of non-negative integers,

$$\frac{\mathbb{E}_G[Y_n^{(s)} X_{1j_1} \cdots X_{mnj_m}]}{\mathbb{E}_G[Y_n^{(s)}]} \to \prod_{i=1}^{m} \left( \lambda_i (1 + \delta_i^{(s)}) \right)^{j_i} \text{ as } n \to \infty; \quad (27)$$

(A3) $\sum_i \lambda_i (\delta_i^{(s)})^2 < \infty$;

(A4) $\frac{\mathbb{E}_G[(Y_n^{(s)})^2]}{(\mathbb{E}_G[Y_n^{(s)}])^2} \leq \exp \left( \sum_i \lambda_i (\delta_i^{(s)})^2 \right) + o(1) \text{ as } n \to \infty$;

Then, the following conclusions hold:

(C1) Let $r(n)$ be a function such that $r(n) \to 0$ as $n \to \infty$. For each $s \in S$, it holds that $Y_n^{(s)} > r(n) \mathbb{E}_G[Y_n^{(s)}]$ asymptotically almost surely.

(C2) For $s \in S$,

$$\frac{Y_n^{(s)}}{\mathbb{E}_G[Y_n^{(s)}]} \Rightarrow W^{(s)} = \prod_i \left[ 1 + \delta_i^{(s)} \right] Z_i \exp \left( -\lambda_i \delta_i^{(s)} \right). \quad (28)$$

This and the convergence in (A1) hold jointly. The infinite product defining $W^{(s)}$ converges a.s. and in $L^2$, with

$$\mathbb{E}[W^{(s)}] = 1 \text{ and } \mathbb{E}[(W^{(s)})^2] = \lim_{n \to \infty} \mathbb{E}_G[(Y_n^{(s)})^2] / (\mathbb{E}_G[Y_n^{(s)}])^2.$$

Moreover, $W^{(s)} > 0$ a.s. iff $\delta_i^{(s)} > -1$ for all $i$;

To draw an alignment with the discussion above, the random variables $Y_n^{(s)}$ are those we are interested in obtaining “concentration” type results, where $s$ is simply an index allowing us to treat simultaneously more than one random variables. In our setting, for $G \sim G_n^r$, $Y_n^{(s)}$ are going to be the conditioned partition functions $Z_{G}^{\alpha,\beta}$ over all dominant phases $(\alpha, \beta)$. The random variables $X_{in}$, for graphs with no small multicyclic components, correspond to cycles of length $i$. For example, in our setting and because the graph $G$ is bipartite, $X_{in}$ is the number of cycles of length $2i$ in $G$.

The conclusion (C1) of Theorem 17 is essentially due to [46], while the conclusion (C2) is due to [25]. Notice that (C2) implies (C1). At this point, to obtain Lemma 33 (which was the important part to prove Theorem 31) we will not explicitly use neither of (C1) and
but rather the following variant, which was implicit in the arguments of [46]. The
variant is also observed in [25, p.5], who discusses it without proof in a specific setting,
and as such we write and prove a formal statement in the setup of Theorem 17. The proof
follows Janson’s proof of Theorem 17 but uses a slightly different finish.

**Lemma 18.** Assume that the conditions in Theorem 17 hold. For an integer \( m > 0 \) and \( s \in S \), let

\[ W^{(s)}_{mn} = \prod_{i=1}^{m} (1 + \delta_i^{(s)}) X_i e^{(-\lambda_i \delta_i^{(s)})}. \]

Then, for every \( \varepsilon > 0 \), it holds that

\[
\lim_{m \to \infty} \limsup_{n \to \infty} \Pr_{G_n} \left( \bigcup_{s \in S} \left[ \frac{Y_n^{(s)}}{E_{G_n}[Y_n^{(s)}]} - W^{(s)}_{mn} > \varepsilon \right] \right) = 0.
\]

(29)

**Proof of Lemma 18.** We prove the statement for a fixed \( s \in S \), the extension of the argument to prove (29) is straightforward (e.g. by a union bound) and is omitted. To lighten notation we will drop \( s \) from the notation and wlog we also assume \( E_{G_n}[Y_n] = 1 \). We will prove that

\[
\limsup_{n \to \infty} \Pr_{G_n} \left( |Y_n - W_{mn}| > \varepsilon \right) \leq \frac{1}{4} \varepsilon^{-2} \left[ \exp \left( \sum_{i=1}^{\infty} \lambda_i \delta_i^2 \right) - \exp \left( \sum_{i=1}^{m} \lambda_i \delta_i^2 \right) \right].
\]

(30)

This clearly gives the statement of the lemma, since by assumption (A3) of Theorem 17,
the lhs is finite and goes to 0 as \( m \to \infty \). To prove (30), we follow [25, Proof of Theorem 1]
up to a certain point but avoid the use of Skorokhod’s theorem in the argument. Janson’s
proof goes as follows. For a positive integer \( m \) define the functions

\[
f_n(x_1, \ldots, x_m) = E_{G_n}[Y_n \mid X_{1n} = x_1, \ldots, X_{mn} = x_m],
\]

\[
f_\infty(x_1, \ldots, x_m) = \lim_{n \to \infty} f_n(x_1, \ldots, x_m) = \prod_{i=1}^{m} (1 + \delta_i) x_i e^{-\lambda_i \delta_i}.
\]

(31)

The second equality follows by assumption (A2) of Theorem 17 and [25, Lemma 1]. Define
also the random variable

\[
Y_{n}^{(m)} = E_{G_n}[Y_n \mid X_{1n}, \ldots, X_{mn}].
\]

Using assumptions (A1) and (A2), Fatou’s Lemma and that \( Y_{n}^{(m)} \) is a conditional expecta-
tion of \( Y_n \), one obtains

\[
\limsup_{n \to \infty} E_{G_n} \left[ |Y_n - Y_{n}^{(m)}|^2 \right] \leq \exp \left( \sum_{i=1}^{\infty} \lambda_i \delta_i^2 \right) - \exp \left( \sum_{i=1}^{m} \lambda_i \delta_i^2 \right),
\]

50
see [25, Equation (5.2)] for details. We now give the main deviation point from Janson’s proof, which amounts to proving that for fixed $m$, we have

$$\lim_{n \to \infty} \Pr_{\mathcal{G}_n}(\{|Y_n^{(m)} - W_{mn}| > \varepsilon\}) = 0.$$  

(32)

as $n \to \infty$. Fix $M > 0$. By (31), there is $N$ such that for $n \geq N$ it holds that

$$|f_n(x_1, \ldots, x_m) - f_\infty(x_1, \ldots, x_m)| < \varepsilon$$

for all integer $x_1, \ldots, x_m \in [0, M]$.

It follows that for $n \geq N$, we have

$$\Pr_{\mathcal{G}_n}(\{|Y_n^{(m)} - W_{mn}| > \varepsilon\}) \leq \Pr_{\mathcal{G}_n}(\bigcup_{i=1}^m [X_i > M])$$

Note that as $n \to \infty$, the rhs by assumption (A1) converges to $\Pr\left(\bigcup_{i=1}^m [Z_i > M]\right)$. The latter can be made arbitrarily small by letting $M \to \infty$. This proves (32).

The final step is to bound

$$\limsup_{n \to \infty} \Pr_{\mathcal{G}_n}(\{|Y_n - W_{mn}| > \varepsilon\})$$

$$\leq \limsup_{n \to \infty} \Pr_{\mathcal{G}_n}(\{|Y_n - Y_n^{(m)}| > \varepsilon/2\}) + \limsup_{n \to \infty} \Pr_{\mathcal{G}_n}(\{|Y_n^{(m)} - W_{mn}| > \varepsilon/2\})$$

$$\leq \frac{1}{4} \varepsilon^{-2}\left[\exp\left(\sum_{i=1}^\infty \lambda_i \delta_i^2\right) - \exp\left(\sum_{i=1}^m \lambda_i \delta_i^2\right)\right] + 0,$$

which finishes the proof of (30). $\square$

2.4 Notes

We refer the reader to the survey of Wormald [54] for a thorough account of models of random regular graphs. Another standard source is the book of Bollobás [6]. For an account which is targeted towards applications for factor models, look at [38, Chapter 9].
CHAPTER III

SECOND MOMENT ANALYSIS USING MATRIX NORMS

In Chapter 2, for a $q$-spin system with interaction matrix $B$, we viewed the partition function of a random $\Delta$-regular bipartite graph as a random variable and calculated its first and second moments. In particular, we saw that the exponential order of the moments is determined by certain functions $\Psi_1$ and $\Psi_2$ of the spin frequencies.

In this chapter, we use the first moment to identify the configurations with the largest contribution in expectation; essentially, we characterize in a suitable sense the configurations which are "candidates" to be the modes in the Gibbs distribution. As was demonstrated in [43] (in the case of the hard-core model), these candidate modes correspond to fixpoints of the tree recursions and we shall show a derivation in our setting. More importantly, we will use this information to reformulate the first moment as an induced matrix norm (depending on $\Delta$) of the interaction matrix $B$.

Of course, there is no a priori reason that the expectation argument of the previous paragraph indeed gives the modes in the Gibbs distribution. We supplement it by showing that the exponential order of the second moment matches the exponential order of the first moment squared. This is done in a surprisingly straightforward way; we observe that the second moment can also be reformulated as the induced matrix norm of $B \otimes B$. Using that induced matrix norms are multiplicative over tensor products, the desired alignment between the second moment and the first moment squared is obtained.

A far more refined variance analysis in Chapter 4 (based on the small subgraph conditioning method) will yield that the identified configurations are indeed the (only) modes in the Gibbs distribution with high probability over the choice of the random graph. To carry out however the variance analysis, we will need more information about the moments and, in particular, the second order behavior of the functions $\Psi_1, \Psi_2$ around their maxima.
We will connect this problem to the stability of fixpoints to the tree recursions, a connection which will be amply utilized to study the modes for spin models of specific interest in Chapter 6.

3.1 Preliminaries

3.1.1 Recap: First and Second Moments

For a $q$-spin system with interaction matrix $B$, our goal is to understand the Gibbs distribution on a random $\Delta$-regular bipartite graph $G = (V, E)$ (with partition $V = V_1 \cup V_2$) by looking at the distribution of spin values in $V_1$ and $V_2$. Let $n = |V_1| = |V_2|$. For a configuration $\sigma : V \to [q]$, we denote the set of vertices assigned spin $i$ by $\sigma^{-1}(i)$. For $q$-dimensional probability vectors $\alpha, \beta$, let

$$
\Sigma^{\alpha, \beta} = \{ \sigma : V \to \{1, \ldots, q\} \mid |\sigma^{-1}(i) \cap V_1| = \alpha_i n, |\sigma^{-1}(i) \cap V_2| = \beta_i n \text{ for } i = 1, \ldots, q \},
$$

that is, configurations in $\Sigma^{\alpha, \beta}$ assign $\alpha_i n$ and $\beta_i n$ vertices in $V_1$ and $V_2$ the spin value $i$, respectively. We will be interested in the total weight $Z_G^{\alpha, \beta}$ of configurations in $\Sigma^{\alpha, \beta}$, namely

$$
Z_G^{\alpha, \beta} = \sum_{\sigma \in \Sigma^{\alpha, \beta}} w(\sigma).
$$

We study $Z_G^{\alpha, \beta}$ by looking at the moments $\mathbb{E}_G[Z_G^{\alpha, \beta}]$ and $\mathbb{E}_G[(Z_G^{\alpha, \beta})^2]$, where the expectation is over the distribution of the random $\Delta$-regular bipartite graph, from hereon denoted by $G$.

Denote the leading term of the first and second moments as:

$$
\Psi_1(\alpha, \beta) = \Psi_1^B(\alpha, \beta) := \lim_{n \to \infty} \frac{1}{n} \log \mathbb{E}_G[Z_G^{\alpha, \beta}],
$$

$$
\Psi_2(\alpha, \beta) = \Psi_2^B(\alpha, \beta) := \lim_{n \to \infty} \frac{1}{n} \log \mathbb{E}_G[(Z_G^{\alpha, \beta})^2].
$$

We will be interested in the global maximizers of $\Psi_1$, which (at least in expectation) capture the configurations which have the largest contribution in the partition function of a random $\Delta$-regular bipartite graph. We also recall the following definition from Section 1.3.

**Definition 5.** For a $q$-spin system with interaction matrix $B$, a dominant phase is a pair $(\alpha, \beta)$ of $q$-dimensional probability vectors which maximize $\Psi_1(\alpha, \beta)$. 

53
3.1.2 Basic Definitions: Matrix Norms

We will reformulate the maxima of the first and second moments in terms of matrix norms. We recall here the basic definitions regarding matrix norms. The usual vector norms are denoted as:

$$\|x\|_p = \left( \sum_{i=1}^{n} x_i^p \right)^{1/p}.$$  

We will use the subordinate matrix norm (also known as the induced matrix norm) which will be denoted as $\| \cdot \|_{p \rightarrow q'}$ (this is different than the usual notation $\| \cdot \|_{p \rightarrow q}$ used in the literature, since we have reserved $q$ for the number of spins) and is defined as:

$$\|A\|_{p \rightarrow q'} = \max_{\|x\|_p = 1} \|Ax\|_{q'}.$$  

Note that if $A$ has non-negative entries then one can restrict the maximization to $x$ with non-negative entries. A well-known example of an induced norm is the spectral norm $\| \cdot \|_{2 \rightarrow 2}$.

3.2 Tree recursions, first moment, and matrix norms

A key component in our arguments is to get a good handle on the function $\Psi_1$. We displayed in Section 1.3.2 that the important idea is to define a new function $\Phi$ which captures in an appropriate way the maximum of $\Psi_1$. The function $\Phi$ allows us to use matrix norms in our analysis of the first and second moments. For the reader’s convenience, we recall next the definition of the function $\Phi$.

Let $p = \Delta / (\Delta - 1)$. For non-negative $q$-dimensional vectors $r := (R_1, \ldots, R_q)$, $c := (C_1, \ldots, C_q)$, define $\Phi(r, c)$ by:

$$\exp \left( \Phi(r, c) / \Delta \right) = \frac{r^\top B c}{\|r\|_p \|c\|_p}.$$  

We will show that the critical points of $\Phi$ and $\Psi_1$ match in the sense that there is a one-to-one correspondence between them and their values are equal at the corresponding critical points. The full statement is contained in Theorem 5 given below, but the important element for the analysis of the second moment is captured in the following lemma:

**Lemma 19.** For every model on bipartite random regular graphs, it holds that

$$\max_{\alpha, \beta \in \Delta_q} \Psi_1(\alpha, \beta) = \max_{r, c} \Phi(r, c).$$  

54
Therefore, to determine the dominant phases of $\Psi_1$, it suffices to study $\Phi$. As we displayed in Section 1.3.2, the maximum of $\Phi$ can be compactly expressed in terms of matrix norms. Recall the one-line derivation:

$$\max_{r,c} \exp \left( \frac{\Phi(r,c)}{\Delta} \right) = \max_c \max_r \frac{r^\top Bc}{\|r\|_p \|c\|_p} = \max_c \frac{\|Bc\|_\Delta}{\|c\|_p} = \|B\|_{p \rightarrow \Delta},$$

(10)

where the second equality follows from matrix norm duality.

Hence, the dominant phases of $\Psi_1$ can be expressed in terms of matrix norms:

$$\max_{\alpha,\beta \in \Delta_q} \exp \left( \frac{\Psi_1(\alpha,\beta)}{\Delta} \right) = \|B\|_{\frac{\Delta}{\Delta-1} \rightarrow \Delta}. \quad (33)$$

The proof of Lemma 19 is immediate using Theorem 5 stated in Section 1.3.2. We reiterate the theorem for the reader’s convenience, and prove it in the remainder of this section. Provided that the reader is willing to believe temporarily Theorem 5, we note that the analysis of the second moment does not need any extra pieces other than Lemma 19.

**Theorem 5.** There is a one-to-one correspondence between the fixpoints of the tree recursions and the critical points of $\Phi$ (both considered for $R_i \geq 0, C_j \geq 0$ in the projective space, that is, up to scaling by a constant).

The following transformation $$(r,c) \mapsto (\alpha,\beta)$$ given by:

\[
\alpha_i = \frac{R_i^{\Delta/(\Delta-1)}}{\sum_i R_i^{\Delta/(\Delta-1)}} \quad \text{and} \quad \beta_j = \frac{C_j^{\Delta/(\Delta-1)}}{\sum_j C_j^{\Delta/(\Delta-1)}} \quad (11)
\]

yields a one-to-one-to-one correspondence between the critical points of $\Phi$ and the critical points of $\Psi_1$ (in the region defined by $\alpha_i \geq 0, \beta_j \geq 0$ and $\sum_i \alpha_i = 1, \sum_j \beta_j = 1$).

Moreover, for the corresponding critical points $(r,c)$ and $(\alpha,\beta)$ one has

$$\Phi(r,c) = \Psi_1(\alpha,\beta). \quad (12)$$

Finally, for ergodic $B$ (irreducible and ergodic), the local maxima of $\Phi$ and $\Psi_1$ happen at the critical points (that is, there are no local maxima on the boundary).

In the following proof of Theorem 5, we give forward references to the ingredients which we will prove next.
Proof of Theorem 5. Lemmas 22 and 23 give the connection between the critical points of \( \Psi_1 \) and the fixpoints of the tree recursions. Lemmas 24 and 25 give the connection between the critical points of \( \Psi_1 \) and \( \Phi \) and show that the values agree on the corresponding critical points. Finally, Lemmas 26 and 27 show that the maxima happen in the interior (that is, for \( R_i > 0, C_j > 0 \) in the case of \( \Phi \) and for \( \alpha_i > 0, \beta_j > 0 \) in the case of \( \Psi_1 \)). \( \square \)

3.2.1 Preliminaries on maximum-entropy distributions

Let \( \alpha \) and \( \beta \) be non-negative vectors in \( \mathbb{R}^q \) such that

\[
\sum_i \alpha_i = 1 \quad \text{and} \quad \sum_j \beta_j = 1. \tag{34}
\]

For \( \alpha \) and \( \beta \) that satisfy (34) let

\[
g(\alpha_1, \ldots, \alpha_q, \beta_1, \ldots, \beta_q) = \max \sum_i \sum_j x_{ij} (\ln(B_{ij}) - \ln x_{ij}), \tag{35}
\]

where the maximum is taken over non-negative \( x_{ij} \)'s such that

\[
\alpha_i = \sum_j x_{ij} \quad \text{and} \quad \beta_j = \sum_i x_{ij}. \tag{36}
\]

Lemma 20. The maximum of the right-hand-side of (35) is achieved at unique \( x_{ij} \). The \( x_{ij} \) are given by

\[
x_{ij} = B_{ij} R_i C_j, \tag{37}
\]

where \( r \) and \( c \) satisfy

\[
R_i \sum_{j=1}^q B_{ij} C_j = \alpha_i \quad \text{and} \quad C_j \sum_{i=1}^q B_{ij} R_i = \beta_j, \tag{38}
\]

and

\[
\sum_{j=1}^q B_{ij} C_j = 0 \implies R_i = 0; \tag{39}
\]

\[
\sum_{i=1}^q B_{ij} R_i = 0 \implies C_j = 0.
\]

The value of \( g \), in terms of \( R_i \)'s and \( C_j \)'s, is given by

\[
g(\alpha_1, \ldots, \alpha_q, \beta_1, \ldots, \beta_q) = -\sum_{i=1}^q \sum_{j=1}^q B_{ij} R_i C_j \ln(R_i C_j). \tag{40}
\]
Proof. From strict concavity of \(-x \ln x\) it follows that the right-hand side of (35) has a unique critical point (if there were two critical points then the segment between the points lies in the linear space defined by (36); the function has a zero derivative on both ends of the segment; and the second derivative of the function is negative on the segment; a contradiction).

Using the method of Lagrange multipliers we obtain that the critical points of the right-hand side of (35) are \(x_{ij}\) given by (37) where \(R_i\)’s and \(C_j\)’s are solutions of (38). We can make any solution of (38) satisfy (39): if \(\sum_{j=1}^q B_{ij} C_j = 0\) then set \(R_i = 0\) (and symmetrically, if \(\sum_{i=1}^q B_{ij} R_i = 0\) then set \(C_j = 0\)). We now argue that this change does not violate (38). Suppose that after the change for some \(k \in [q]\) we have

\[
R_k \sum_{j=1}^q B_{kj} C_j \neq \alpha_k. \tag{41}
\]

Then \(i = k\) (since only \(R_i\) changed) and since \(\sum_{j=1}^q B_{ij} C_j = 0\) we also have \(\alpha_i = 0\), a contradiction (with (41)). Now suppose that after the change for some \(j \in [q]\) we have

\[
C_j \sum_{k=1}^q B_{kj} R_k \neq \beta_j. \tag{42}
\]

Then \(B_{ij} > 0\) and \(C_j > 0\) (otherwise changing \(R_i\) would not violate (42)). This then implies \(\sum_{j=1}^q B_{ij} C_j > B_{ij} C_j > 0\), a contradiction. Thus the change does not violate (38).

Equation (40) is obtained by substituting (38) into (35).

Remark 6. Scaling all the \(R_i\)’s up by the same factor while scaling all the \(C_j\)’s down by the same factor preserves (37) and (38). Modulo such scaling the \(R_i\)’s and \(C_j\)’s are unique, since the \(x_{ij}\)’s are unique and (37) determines the \(R_i\)’s and \(C_j\)’s once one value (say \(R_1\)) is fixed (here we use the fact that the matrix of the model is ergodic).

Remark 7. Note that the condition (34) translates (using (38)) into the following condition on \(R_i\)’s and \(C_j\)’s

\[
\sum_{i=1}^q \sum_{j=1}^q B_{ij} R_i C_j = 1. \tag{43}
\]

Our goal now is to see how the value of (35) changes when we perturb \(\alpha_i\)’s and \(\beta_j\)’s. We are going to view them as functions of a new variable \(z\). All differentiation in this section
will be with respect to \( z \). Note that to stay in the subspace defined by (34) we should have, in particular,
\[
\sum_i \alpha_i' = \sum_i \alpha_i'' = 0 \quad \text{and} \quad \sum_j \beta_j' = \sum_j \beta_j'' = 0. \tag{44}
\]

Differentiating (38) we obtain
\[
\sum_{j=1}^q B_{ij}(R_i C_j)' = \alpha_i' \quad \text{and} \quad \sum_{i=1}^q B_{ij}(R_i C_j)' = \beta_j'. \tag{45}
\]

The following ratio of (38) and (45) will be useful later
\[
\frac{\alpha_i'}{\alpha_i} = \frac{R_i'}{R_i} + \sum_{j=1}^q B_{ij} C_j' \quad \text{and} \quad \frac{\beta_j'}{\beta_j} = \frac{C_j'}{C_j} + \sum_{i=1}^q B_{ij} R_i'. \tag{46}
\]

The scaling freedom for \( R_i \)'s and \( C_j \)'s (discussed in Remark 6) is equivalent to increasing all \( R_i'/R_i \)'s by the same (additive) amount and decreasing all \( C_j'/C_j \)'s by the same (additive) amount. We are going to remove this freedom by requiring
\[
\sum_{i=1}^q \frac{R_i'}{R_i} = \sum_{j=1}^q \frac{C_j'}{C_j}. \tag{47}
\]

(Recall that we study the effect of perturbing \( g \) when we change \( \alpha_i \)'s and \( \beta_j \)'s; equation (47) just fixes the corresponding change in \( R_i \)'s and \( C_j \)'s.)

Now we compute the derivatives of \( g \).

**Lemma 21.** We have
\[
g' = -\sum_{i=1}^q (\ln R_i)\alpha_i' - \sum_{j=1}^q (\ln C_j)\beta_j', \tag{48}
\]

and
\[
g'' = -\sum_{i=1}^q \frac{R_i'}{R_i} \alpha_i' - \sum_{j=1}^q \frac{C_j'}{C_j} \beta_j' - \sum_{i=1}^q (\ln R_i)\alpha_i'' - \sum_{j=1}^q (\ln C_j)\beta_j''. \tag{49}
\]

**Proof.** Using \((f \ln f)' = (1 + \ln f)f'\) and equations (45) and (44) we obtain
\[
g' = -\sum_{i=1}^q \sum_{j=1}^q B_{ij}(1 + \ln(R_i C_i))(R_i C_j)' = -\sum_{i=1}^q (\ln R_i)\alpha_i' - \sum_{j=1}^q (\ln C_j)\beta_j'.
\]

Differentiating (48) we obtain (49). \( \square \)

Note the expressions (48) and (49) are independent of the choice of scaling of \( R_i \)'s and \( C_j \)'s (this follows from (44)). The particular tying of \( R_i'/R_i \)'s and \( C_j'/C_j \)'s to \( \alpha_i' \) and \( \beta_j' \) (given by (47)) will be useful later.
3.2.2 Critical points of $\Psi_1$ and the tree recursions

In this section we establish the connection between the critical points of $\Psi_1$ and the fixpoints of the tree recursions.

**Lemma 22.** Let $\alpha, \beta$ be a critical point of $\Psi_1(\alpha, \beta)$ in the subspace defined by (34). Let $r, c$ be given by (38). Then

$$\alpha_i \propto R_i^{\Delta / (\Delta - 1)} \quad \text{and} \quad \beta_j \propto C_j^{\Delta / (\Delta - 1)}. \quad (50)$$

Consequently, $r, c$ satisfy the tree recursions stated in the introduction:

$$R_i \propto \left( \sum_{j=1}^{q} B_{ij} C_j \right)^{\Delta - 1} \quad \text{and} \quad C_j \propto \left( \sum_{i=1}^{q} B_{ij} R_i \right)^{\Delta - 1}. \quad (8)$$

**Proof.** At the critical points of $\Psi$ the first derivative of $\Psi$ has to vanish for all $\alpha_i'$'s and $\beta_j'$'s from the subspace defined by (44), that is,

$$\Psi' = (\Delta - 1) \left( \sum_{i=1}^{q} (1 + \ln \alpha_i) \alpha_i' + \sum_{j=1}^{q} (1 + \ln \beta_j) \beta_j' \right) - \Delta \left( \sum_{i=1}^{q} (\ln R_i) \alpha_i' + \sum_{j=1}^{q} (\ln C_j) \beta_j' \right)$$

$$= \sum_{i=1}^{q} ((\Delta - 1)(1 + \ln \alpha_i) - \Delta \ln R_i)\alpha_i' + \sum_{j=1}^{q} ((\Delta - 1)(1 + \ln \beta_j) - \Delta \ln C_j)\beta_j' = 0, \quad (51)$$

where the $R_i$'s and $C_j$'s are given by (38). Inspecting (51) we see that $(\Delta - 1)(1 + \ln \alpha_i) - \Delta \ln R_i$ have the same value. Indeed, if two of them, say with indices $i_1, i_2$, had different values then we could increase $\alpha_{i_1}$ and decrease $\alpha_{i_2}$ by the same infinitesimal amount and violate (51). Similarly, $(\Delta - 1)(1 + \ln \beta_j) - \Delta C_j$ have the same value and hence we have (50).

Plugging (50) into (38) one obtains (8). \qed

**Lemma 23.** Let $(r, c)$ be a solution of the tree recurrences (8). Let $(\alpha, \beta)$ be given by (11). Then $(\alpha, \beta)$ is a critical point of $\Psi_1(\alpha, \beta)$ in the subspace defined by (34).

**Proof.** Let

$$Z_R := (\Delta - 1)(1 + \ln \alpha_i) - \Delta \ln R_i = (\Delta - 1) \left( 1 - \ln \sum_{i=1}^{q} R_i^{(\Delta + 1)/\Delta} \right),$$
where the second equality follows from (11). Note that $Z_R$ is independent of the choice of $i$. Similarly let

$$Z_C := (\Delta - 1)(1 + \ln \beta_j) - \Delta \ln C_j = (\Delta - 1)\left(1 - \ln \sum_{j=1}^{q} C_j^{(\Delta+1)/\Delta}\right).$$

For perturbations of $\alpha, \beta$ in the subspace given by (34) we have

$$\Psi'_{1}(\alpha, \beta) = \sum_{i=1}^{q} ((\Delta - 1)(1 + \ln \alpha_i) - \Delta \ln R_i) \alpha'_i + \sum_{j=1}^{q} ((\Delta - 1)(1 + \ln \beta_j) - \Delta \ln C_j) \beta'_j$$

$$= Z_R \sum_{i=1}^{q} \alpha'_i + Z_C \sum_{j=1}^{q} \beta'_j = 0,$$

and hence $(\alpha, \beta)$ is a critical point. $\square$

### 3.2.3 Value of $\Psi_1$ at the critical points

**Lemma 24.** Let $(\alpha, \beta)$ be critical point of $\Psi_1(\alpha, \beta)$. Let $(r, c)$ be given by (38). Then

$$\Phi(r, c) = \Psi_1(\alpha, \beta).$$

Moreover, $(r, c)$ is a critical point of $\Phi(r, c)$.

**Proof.** We have (see equation (40))

$$\Psi_1(\alpha, \beta) = (\Delta - 1)\left(\sum_{i=1}^{q} \alpha_i \ln \alpha_i + \sum_{j=1}^{q} \beta_j \ln \beta_j\right) - \Delta \sum_{i=1}^{q} \sum_{j=1}^{q} B_{ij} R_i C_j \ln(R_i C_j).$$

At the critical points we have (see equation (50))

$$\alpha_i = \frac{R_i^{\Delta/(\Delta-1)}}{\sum_{i=1}^{q} R_i^{\Delta/(\Delta-1)}} \quad \text{and} \quad \beta_j = \frac{C_j^{\Delta/(\Delta-1)}}{\sum_{j=1}^{q} C_j^{\Delta/(\Delta-1)}}.$$

Plugging (38) into (52) we obtain

$$\Psi_1(\alpha, \beta) = (\Delta - 1)\left(\sum_{i=1}^{q} \alpha_i \ln \alpha_i + \sum_{j=1}^{q} \beta_j \ln \beta_j\right) - \Delta \left(\sum_{i=1}^{q} \alpha_i \ln R_i + \sum_{j=1}^{q} \beta_j \ln C_j\right) =$$

$$\sum_{i=1}^{q} \alpha_i \ln \frac{\alpha_i^{\Delta-1}}{R_i^\Delta} + \sum_{j=1}^{q} \beta_j \ln \frac{\beta_j^{\Delta-1}}{C_j^\Delta} = -(\Delta - 1)\left[\ln \left(\sum_{i=1}^{q} R_i^{\Delta/(\Delta-1)}\right) + \ln \left(\sum_{j=1}^{q} C_j^{\Delta/(\Delta-1)}\right)\right],$$

where in the last equality we used (53) and the fact that $\alpha_i$’s and $\beta_j$’s sum to 1. Recall that

$$\sum_{i=1}^{q} \sum_{j=1}^{q} B_{ij} R_i C_j = \sum_{i=1}^{q} \alpha_i = 1,$$

60
and hence the following is obtained by adding zero to the right-hand side of (54)

\[ \Psi_1(\alpha, \beta) = \Delta \ln \left( \frac{q}{q} \sum_{j=1}^{q} B_{ij} R_i C_j \right) - (\Delta - 1) \left[ \ln \left( \frac{q}{q} \sum_{i=1}^{q} R_i^{\Delta/(\Delta-1)} \right) + \ln \left( \frac{q}{q} \sum_{j=1}^{q} C_j^{\Delta/(\Delta-1)} \right) \right] = \Phi(r, c). \]

Now we argue that \((r, c)\) is a critical point of \(\Phi(r, c)\). We have

\[ \frac{\partial}{\partial R_i} \Phi(r, c) = \Delta \frac{\sum_{j=1}^{q} B_{ij} C_j}{\sum_{i=1}^{q} \sum_{j=1}^{q} B_{ij} R_i C_j} - (\Delta - 1) \frac{\Delta \sum_{i=1}^{q} R_i^{1/(\Delta-1)}}{\sum_{i=1}^{q} R_i^{1/(\Delta-1)}}. \]

Using (53), (38), and (34) we obtain

\[ \frac{\partial}{\partial R_i} \Phi(r, c) = \Delta \frac{\alpha_i R_i}{R_i} - \Delta \frac{\alpha_i}{R_i} = 0. \]

The same argument yields

\[ \frac{\partial}{\partial C_j} \Phi(r, c) = \Delta \frac{\sum_{i=1}^{q} B_{ij} R_i}{\sum_{i=1}^{q} \sum_{j=1}^{q} B_{ij} R_i C_j} - (\Delta - 1) \frac{\Delta \sum_{j=1}^{q} C_j^{1/(\Delta-1)}}{\sum_{i=1}^{q} C_j^{1/(\Delta-1)}}. \]

and hence \((r, c)\) is a critical point of \(\Phi\).

**Lemma 25.** Let \((r, c)\) be a critical point of \(\Phi(r, c)\). Let \(\alpha, \beta\) be given by (11). Then \(\alpha, \beta\) is a critical point of \(\Psi_1(\alpha, \beta)\) in the subspace defined by (34).

**Proof.** At a critical point of \(\Phi\) we have that (56) is zero for \(i \in [q]\). Note that the denominators do not depend on \(i\) and hence we have

\[ R_i^{1/(\Delta-1)} \propto \sum_{j=1}^{q} B_{ij} C_j. \]

Similarly, from (57) we obtain

\[ C_j^{1/(\Delta-1)} \propto \sum_{i=1}^{q} B_{ij} R_i. \]

Hence \((r, c)\) satisfy the tree recursions. Now we use Lemma 23 to conclude that \((\alpha, \beta)\) is a critical point of \(\Psi_1(\alpha, \beta)\) in the subspace defined by (34).

### 3.2.4 Local maxima of \(\Psi_1\) are in the interior

In this section we show that for models with ergodic (irreducible and aperiodic) interaction matrix \(B\) the maximum of \(\Phi(r, c)\) is achieved in the interior. A symmetric matrix is irreducible if the graph whose edges correspond to non-zero edges of \(B\) is connected. A symmetric matrix is aperiodic if the graph whose edges correspond to non-zero edges of \(B\) has an odd cycle.
Lemma 26. Assume that $B$ is ergodic. Let $(r, c) \neq 0$ be a local maximum of $\Phi$ in the region $r, c \geq 0$. Then $R_i > 0$ for all $i \in [q]$ and $C_j > 0$ for all $j \in [q]$.

Proof. Suppose not, that is, we have a maximum that has a zero on some coordinate of $r$ or $c$. From the ergodicity of $B$ we have that there exist $i, j \in [q]$ such that i) $R_i = 0$, $C_j > 0$, and $B_{ij} > 0$ or ii) $R_i > 0$, $C_j = 0$, and $B_{ij} > 0$. (Suppose not. Let $Z_R \subseteq [q]$ be the set of $i$ such that $R_i = 0$. Similarly let $Z_C \subseteq [q]$ be the set of $j$ such that $C_j = 0$. If neither i) nor ii) happens then non-zero $B_{ij}$ are possibly between $i \in Z_R$ and $j \in Z_C$ and $i \in [q] \setminus Z_R$ and $j \in [q] \setminus Z_C$. Thus in $B^2$ the non-zero $(B^2)_{ij}$ are possibly between $i, j \in Z_R$ and $i, j \in [q] \setminus Z_R$. Thus $B$ is not ergodic.) W.l.o.g. assume that it is the case i) (the case ii) is handled analogously).

The derivative of $\Phi$ w.r.t. $R_i$ is (we are using $R_i = 0$)

$$\frac{\partial}{\partial R_i} \Phi(r, c) = \Delta \frac{\sum_{j=1}^{q} B_{ij} C_j}{\sum_{i=1}^{q} \sum_{j=1}^{q} B_{ij} R_i C_j} > \Delta \frac{\sum_{i=1}^{q} \sum_{j=1}^{q} B_{ij} C_j}{\sum_{j=1}^{q} B_{ij} R_i C_j} > 0,$$

and hence we are not at a maximum, a contradiction. \hfill \Box

Lemma 27. Assume that $B$ is ergodic. Let $\alpha, \beta \geq 0$ be a local maximum of $\Psi_1(\alpha, \beta)$ in the subspace defined by (34). Then $\alpha_i > 0$ for all $i \in [q]$ and $\beta_j > 0$ for all $j \in [q]$.

Proof. It will be useful to view $\Psi_1$ as a function of $(r, c)$. Because of Lemma 20 we have $(r, c)$ satisfying (55) and (39) (and any such $(r, c)$ yields $(\alpha, \beta)$ satisfying (34)). From (54), we have

$$\Psi_1(\alpha, \beta) = \sum_{i=1}^{q} \sum_{j=1}^{q} B_{ij} R_i C_j \left( (\Delta - 1) \left( \ln \left( \sum_{j=1}^{q} B_{ij} C_j \right) + \ln \left( \sum_{i=1}^{q} B_{ij} R_i \right) \right) - \ln R_i - \ln C_j \right) =: \hat{\Psi}_1(r, c).$$

If $r$ has a zero coordinate then, by ergodicity of $B$ there exists $k, \ell \in [q]$ such that (i) $R_k = 0$, $C_\ell > 0$, and $B_{k\ell} > 0$ or (ii) $R_k > 0$, $C_\ell = 0$, and $B_{k\ell} > 0$ (see the argument in the proof of Lemma 26). W.l.o.g. it is the case (i).

Note that we have

$$\frac{\partial}{\partial R_k} \sum_{i=1}^{q} \sum_{j=1}^{q} B_{ij} R_i C_j = \sum_{j=1}^{q} B_{kj} C_j \geq B_{k\ell} C_\ell > 0. \quad (58)$$
We have
\[
\frac{\partial}{\partial R_k} \hat{\Psi}_1 = \sum_{j=1}^q B_{kj} C_j \left( (\Delta - 1) \ln \left( \sum_{i=1}^q B_{ij} R_i \right) - \ln C_j \right) \\
+ \left( (\Delta - 1) \ln \left( \sum_{j=1}^q B_{kj} C_j \right) - \ln R_k \right) \left( \sum_{j=1}^q B_{kj} C_j \right) + (\Delta - 2) \sum_{j=1}^q B_{kj} C_j. \tag{59}
\]

The first sum in (59) is finite since if $C_j > 0$ then $\sum_{i=1}^q B_{ij} R_i > 0$ (using (39)); if $C_j = 0$ then the contribution of the term to the sum is zero (we are using the usual convention $0 \ln 0 = 0$). The second term in (59) has value $+\infty$ since $\ln R_k = -\infty$ and (58). Finally, the last term in (59) is finite and hence we have $\frac{\partial}{\partial R_k} \hat{\Psi}_1 = +\infty$.

Recall that $C_\ell > 0$ and hence (using (39)):
\[
\frac{\partial}{\partial C_\ell} \sum_{i=1}^q \sum_{j=1}^q B_{ij} R_i C_j = \sum_{i=1}^q B_{i\ell} R_i > 0. \tag{60}
\]

Finally, we argue that $\frac{\partial}{\partial C_\ell} \hat{\Psi}_1$ is finite. We have (analogously to (59))
\[
\frac{\partial}{\partial C_\ell} \hat{\Psi}_1 = \sum_{i=1}^q B_{i\ell} C_i \left( (\Delta - 1) \ln \left( \sum_{j=1}^q B_{ij} C_j \right) - \ln R_i \right) \\
+ \left( (\Delta - 1) \ln \left( \sum_{i=1}^q B_{i\ell} R_i \right) - \ln C_\ell \right) \left( \sum_{i=1}^q B_{i\ell} R_i \right) + (\Delta - 2) \sum_{i=1}^q B_{i\ell} R_i. \tag{61}
\]

The first and third term in (61) are finite by the same argument as for (59). In the second term we use (60) and $C_\ell > 0$.

Now we increase $R_k$ by an infinitesimal amount and change $C_\ell$ to maintain (43) (and hence (34)). (This is possible because both $C_\ell$ and $R_k$ change the value of (43), see equations (58) and (60).) This change will increase $\hat{\Psi}_1$ and hence $\Psi_1$ contradicting the local maximality of $\alpha, \beta$. \hfill \Box

### 3.3 Second Moment Analysis for Dominant Phases

In this section, we will prove Theorem 4, which we restate for convenience here.

**Theorem 4.** For any spin system, for all $\Delta \geq 3$,
\[
\max_{\alpha, \beta} \Psi_2(\alpha, \beta) = 2 \max_{\alpha, \beta} \Psi_1(\alpha, \beta).
\]

In particular, for every dominant phase $(\alpha, \beta)$, it holds that $\Psi_2(\alpha, \beta) = 2 \Psi_1(\alpha, \beta)$.
Theorem 4 is critical for our arguments, since it will eventually allow us to prove strong concentration properties for the random variables $Z^{\alpha,\beta}_G$, whenever $(\alpha, \beta)$ is a dominant phase.

The proof of Theorem 4 resides into two main components: (i) the reformulation of the first moment of any spin system as an induced matrix norm of its interaction matrix $B$, (ii) viewing the second moment as the first moment of a “paired-spin” system with interaction matrix $B \otimes B$. Item (ii) allows us to reformulate the second moment as an induced matrix norm of $B \otimes B$. The key component then is to connect the induced matrix norms of $B$ and $B \otimes B$, which we can do by using multiplicative properties of induced matrix norms over tensor product.

### 3.3.1 The Second Moment as the First Moment of a Paired-Spin model

We have already discussed in Section 2.2.1 that the second moment can be viewed as the first moment of a paired-spin model, see Remark 3. We briefly review the connection.

For the second moment $E_G[(Z^{\alpha,\beta}_G)^2]$, one considers a pair of configurations, say $\sigma$ and $\sigma'$, which are both constrained to have marginals $\alpha$ on $V_1$ and $\beta$ on $V_2$, where $V = V_1 \cup V_2$. We capture this constraint using a pair of vectors $\gamma, \delta$ corresponding to the overlap between $\sigma$ and $\sigma'$, in particular, $\gamma_{ij}$ (and $\delta_{ij}$) is the number of vertices in $V_1$ (and $V_2$, respectively) with spin $i$ in $\sigma$ and spin $j$ in $\sigma'$. Thus, in the second moment, every vertex in $V$ is assigned a pair of spins $(i, k)$ and the interaction in the paired-spin system is given by $B \otimes B$.

Let us now see how this translates to the functions $\Psi^B_1, \Psi^B_2$. Recall, $\Psi^B_1$ indicates the dependence of the function $\Psi_1$ on the interaction matrix $B$; to simplify the notation we will drop the exponent if it is $B$. Extrapolating from Section 2.2.1, we have

\[
\Psi_2(\alpha, \beta) = \max_{\gamma, \delta} \Psi^{B \otimes B}_1(\gamma, \delta),
\]

where the optimization in (62) is constrained to non-negative $\gamma, \delta$ such that

\[
\sum_i \gamma_{ik} = \alpha_k, \quad \sum_k \gamma_{ik} = \alpha_i, \quad \sum_j \delta_{j\ell} = \beta_\ell \quad \text{and} \quad \sum_\ell \delta_{j\ell} = \beta_j.
\]

### 3.3.2 Analyzing the Second Moment: Proof of Theorem 4

We are now ready to prove Theorem 4.
Proof of Theorem 4. Replacing the four constraints in (63) with the weaker constraints \( \gamma, \delta \in \Delta_q \) can only increase the value of (62) and hence

\[
\max_{\alpha, \beta} \exp(\Psi_2(\alpha, \beta)/\Delta) \leq \max_{\gamma, \delta \in \Delta_q} \exp \left( \Psi_1^B(\gamma, \delta)/\Delta \right) = \| B \otimes B \|_{\Delta \to \Delta},
\]  

(64)

where the last equality follows by applying the analogue of (33) for the spin model specified by \( B \otimes B \). The key fact we now use is that for induced norms \( \| \cdot \|_{p \to q'} \) with \( p \leq q \) it holds (c.f., [3, Proposition 10.1]) that:

\[
\| B \otimes B \|_{p \to q'} = \| B \|_{p \to q'} \| B \|_{p \to q'}. \tag{65}
\]

Therefore,

\[
\max_{\alpha, \beta} \Psi_2(\alpha, \beta) \leq 2\Delta \log \| B \|_{\Delta \to \Delta} = 2 \max_{\alpha, \beta} \Psi_1(\alpha, \beta). \tag{66}
\]

Observe that for any \( (\alpha, \beta) \) we have \( \Psi_2(\alpha, \beta) \geq 2\Psi_1(\alpha, \beta) \) as a simple implication of \( E[X^2] \geq E[X]^2 \). This yields the equality in (66), as well as the equality for dominant phases.

\[ \square \]

### 3.3.3 Optimal second moment configuration

We will need more detailed information about the \( \gamma, \delta \) which achieve equality in Theorem 4 and equation (62). The following lemma is true whenever \( B \) is regular (and hence for antiferromagnetic models as well, cf. Definition 10).

**Lemma 28.** Assume that \( B \) is regular. The \( \gamma, \delta \) for which the equality in

\[
\max_{\alpha, \beta} \max_{\gamma, \delta \text{ satisfying } (63)} \Psi_1^B(\gamma, \delta) = \max_{\alpha, \beta} \Psi_1(\alpha, \beta), \tag{67}
\]

is achieved satisfy (for all \( i, j, k, l \in [q] \))

\[
\gamma_{ik} = \alpha_i \alpha_k \quad \text{and} \quad \delta_{jl} = \beta_j \beta_l. \tag{68}
\]

**Proof.** We will have to dig in to the proof of (65) and use (63). Bennett’s proof of (65) is the following (our particular values are \( q' = \Delta \) and \( p = \Delta/(\Delta - 1) \)):

\[
\|(B \otimes B)r\|_{q'} = \left( \sum_k \sum_i \sum_j B_{ij} \sum_l B_{kl} R_{jl} \right)^{1/q'} \leq \|B\|_{p \to q'} \left( \sum_k \left( \sum_j \sum_l \left| B_{kl} R_{jl} \right|^p \right)^{q'/p} \right)^{1/p'} \leq \|B\|_{p \to q'} \left( \sum_j \left( \sum_l \left| R_{jl} \right|^q \right)^{p/q} \right)^{1/p'} \leq \|B\|_{p \to q'}^2 \left( \sum_{j,l} R_{jl} \right)^{1/p}. \tag{66}
\]

65
Note that in the last inequality one uses \( \|B r\|_{q'} \leq \|B\|_{p \to q'} \|r\|_p \), applied to the vectors \( r'_j := (R_{j1}, R_{j2}, \ldots, R_{jq}) \), for \( j = 1, \ldots, q \). Thus if \( r \) is a maximizer of
\[
\max_r \frac{\|(B \otimes B)r\|_{q'}}{\|r\|_p},
\]
then the vectors \( r'_j \) are maximizers of
\[
\max_{r'} \frac{\|B r'\|_{q'}}{\|r'\|_p}.
\]
The same, by symmetry, applies to \( r''_l := (R_{1l}, R_{2l}, \ldots, R_{ql}) \), for \( l = 1, \ldots, q \).

The second inequality in Bennett’s proof is Minkowski’s inequality applied to vectors \( B r'_1, \ldots, B r'_q \). The equality is achieved only if \( B r'_1, \ldots, B r'_q \) generate space of dimension one, and since \( B \) is regular we have also that \( r'_1, \ldots, r'_q \) generate space of dimension one. Hence, for a maximizer \( r \) of (69) we have \( r = r' \otimes r'' \), where \( r' \) and \( r'' \) are maximizers of (70). By Theorem 5 (equation (11)) we then have
\[
\gamma_{ik} = \alpha'_i \alpha''_k,
\]
for the corresponding maximizers of \( \Psi^B_1(\gamma) \) and \( \Psi^B_1(\alpha) \). Equation (71) together with constraints
\[
\sum_i \gamma_{ik} = \alpha_k \quad \text{and} \quad \sum_k \gamma_{ik} = \alpha_i,
\]
implies \( \gamma_{ik} = \alpha_i \alpha_k \) (since \( \alpha_k = \sum_i \gamma_{ik} = \sum_i \alpha'_i \alpha''_k = \alpha''_k \)). The proof of \( \delta_{jl} = \beta_j \beta_l \) is analogous.

3.4 Tree Recursions and Critical Points of the First Moment

The second moment results of the previous section will be used to establish that the Gibbs distribution is concentrated at the global maxima of \( \Psi_1(\alpha, \beta) \). To simplify the analysis of the local maxima of \( \Psi_1 \) we connect them to attractive fixpoints of the associated tree recursions.

In [43], it was observed that the critical points of \( \Psi_1 \) correspond to fixpoints of the following tree recursions (see Section 3.2.2 for a derivation in our setting)
\[
\hat{R}_i \propto \left( \sum_{j=1}^q B_{ij} C_j \right)^{\Delta-1} \quad \text{and} \quad \hat{C}_j \propto \left( \sum_{i=1}^q B_{ij} R_j \right)^{\Delta-1}.
\]
The fixpoints are those \( R_i \)'s and \( C_j \)'s such that \( \hat{R}_i \propto R_i \) and \( \hat{C}_j \propto C_j \), for all \( i,j \in [q] \). In [43], this connection was established for the case for hard-core model, so we give a derivation in our setting in Section 3.2.2.

We call a fixpoint \( x \) of a function \( f \) a Jacobian attractive fixpoint if the Jacobian of \( f \) at \( x \) has spectral radius less than 1. We say that a critical point \( \alpha, \beta \) is a Hessian local maximum if the Hessian of \( \Psi_1 \) at \( \alpha, \beta \) is negative definite. (Note this is a sufficient condition for \( \alpha, \beta \) to be a local maximum.)

The purpose of this section is to prove Theorem 2, which we recall for the convenience of the reader here (cf. Theorem 5 for a more detailed version of the below connection.)

**Theorem 2.** Jacobian attractive fixpoints of the depth two tree recursions (8) correspond to Hessian local maxima of \( \Psi_1 \). Moreover, if \( B \) is ergodic (irreducible and aperiodic), Hessian local maxima of \( \Psi_1 \) correspond to Jacobian attractive fixpoints of the depth two tree recursions.

Theorem 2 is important for analyzing the global maxima of \( \Psi_1 \) for colorings and antiferromagnetic Potts model (see Section 6.3). The rest of this section is devoted to the proof of Theorem 2.

### 3.4.1 Maximum entropy configurations on random \( \Delta \)-regular bipartite graphs

We analyze the critical points by looking at the second derivative. Using \( (f \ln f)'' = (f')^2/f + (1 + \ln f) f'' \) we have

\[
\Psi_1''(\alpha, \beta) = (\Delta - 1) \sum_{i=1}^{q} \left( (\alpha_i')^2/\alpha_i + (1 + \ln \alpha_i)\alpha_i'' \right) - \Delta \sum_{i=1}^{q} \left( \alpha_i' \frac{R_i'}{R_i} + (\ln R_i)\alpha_i'' \right) \\
+ (\Delta - 1) \sum_{j=1}^{q} \left( (\beta_j')^2/\beta_j + (1 + \ln \beta_j)\beta_j'' \right) - \Delta \sum_{j=1}^{q} \left( \beta_j' \frac{C_j'}{C_j} + (\ln C_j)\beta_j'' \right) \\
= (\Delta - 1) \sum_{i=1}^{q} \left( \alpha_i'^2/\alpha_i - \Delta \sum_{i=1}^{q} \alpha_i' \frac{R_i'}{R_i} + \sum_{i=1}^{q} \alpha_i'' \left( (\Delta - 1)(1 + \ln \alpha_i) - \Delta \ln R_i \right) \right) \\
+ (\Delta - 1) \sum_{j=1}^{q} \left( \beta_j'^2/\beta_j - \Delta \sum_{j=1}^{q} \beta_j' \frac{C_j'}{C_j} + \sum_{j=1}^{q} \beta_j'' \left( (\Delta - 1)(1 + \ln \beta_j) - \Delta \ln C_j \right) \right) \\
= (\Delta - 1) \sum_{i=1}^{q} \left( \alpha_i'^2/\alpha_i - \Delta \sum_{i=1}^{q} \alpha_i' \frac{R_i'}{R_i} + (\Delta - 1) \sum_{j=1}^{q} \left( \beta_j'^2/\beta_j - \Delta \sum_{j=1}^{q} \beta_j' \frac{C_j'}{C_j} \right) \right)
\]
where the last equality follows from (51) (replacing \( \alpha'_i \) by \( \alpha''_i \) and \( \beta'_j \) by \( \beta''_j \); note that they are both from the same subspace (44)).

Plugging (46) into (72) we obtain
\[
\Psi''(\alpha, \beta) = \sum_{i=1}^{q} \alpha'_i \left( (\Delta - 1) \sum_{j=1}^{q} \frac{B_{ij} C'_j}{B_{ij} C'_j} - \frac{R'_i}{R_i} \right) + \sum_{j=1}^{q} \beta'_j \left( (\Delta - 1) \sum_{i=1}^{q} \frac{B_{ij} R'_i}{B_{ij} R_i} - \frac{C'_j}{C_j} \right). 
\] (73)

We are going to use the second partial derivative test (which gives a sufficient condition) to establish maxima of \( \Psi_1 \). We will use the following terminology for local maxima established using this method.

**Definition 8.** A critical point \( x \) of a function \( f : \mathcal{M} \to \mathbb{R} \) is called **Hessian local maximum** if the Hessian of \( f \) at \( x \) is negative definite.

Let \( L \) be the (matrix of) linear map \((r_1, \ldots, r_q, c_1, \ldots, c_q) \mapsto (\hat{r}_1, \ldots, \hat{r}_q, \hat{c}_1, \ldots, \hat{c}_q) \) given by
\[
\hat{r}_i = \sum_j B_{ij} R_i C_j / \sqrt{\alpha_i \beta_j} \quad \text{and} \quad \hat{c}_j = \sum_i B_{ij} R_i C_i / \sqrt{\alpha_i \beta_j}. 
\] (74)

In the following, we denote by \( I \) the identity matrix of dimension \( 2q \times 2q \).

**Lemma 29.** A critical point \((\alpha, \beta)\) is a Hessian local maximum of \( \Psi_1(\alpha, \beta) \) in the subspace defined by (44) if and only if \( w^T (I + L)((\Delta - 1)L - I) w < 0 \) for all \( w = (r_1, \ldots, r_q, c_1, \ldots, c_q)^T \) such that
\[
\sum_{i=1}^{q} \sqrt{\alpha_i} r_i = 0 \quad \text{and} \quad \sum_{j=1}^{q} \sqrt{\beta_j} c_j = 0. 
\] (75)

**Proof.** To check whether we are at a Hessian local maximum of \( \Psi(\alpha, \beta) \) we have to have (73) negative for non-zero \( \alpha'_i \)’s and \( \beta'_j \)’s from the subspace defined by (44) and (47).

Let \( r_i = \sqrt{\alpha_i} R_i / R_i \) and \( c_j = \sqrt{\beta_j} C_j / C_j \). Using (46) we have
\[
\Psi'' = \sum_i \alpha'_i \left( \frac{R'_i}{R_i} + \sum_j \frac{B_{ij} C'_j}{B_{ij} C'_j} \right) \left( \Delta - 1 \right) \sum_j \frac{B_{ij} C'_j}{B_{ij} C'_j} - \frac{R'_i}{R_i} 
\]
\[
+ \sum_j \beta'_j \left( \frac{C'_j}{C_j} + \sum_i \frac{B_{ij} R'_i}{B_{ij} R_i} \right) \left( \Delta - 1 \right) \sum_i \frac{B_{ij} R'_i}{B_{ij} R_i} - \frac{C'_j}{C_j} 
\]
\[
= \sum_i \left( r_i + \sum_j \frac{B_{ij} R_i C_j}{\sqrt{\alpha_i \beta_j}} c_j \right) \left( \sum_j (\Delta - 1) \frac{B_{ij} R_i C_j}{\sqrt{\alpha_i \beta_j}} c_j - r_i \right) 
\]
\[
+ \sum_j \left( c_j + \sum_i \frac{B_{ij} R_i C_j}{\sqrt{\alpha_i \beta_j}} r_i \right) \left( \sum_i (\Delta - 1) \frac{B_{ij} R_i C_j}{\sqrt{\alpha_i \beta_j}} r_i - c_j \right). 
\]

68
Let \( w = (r_1, \ldots, r_q, c_1, \ldots, c_q)^\top \). In terms of \( L \) and \( w \) we have

\[
\Phi'' = w^\top (I + L)((\Delta - 1)L - I)w.
\] (76)

We have to examine when (76) is in the subspace defined by (44) and (47), which in terms of \( r_i \)'s and \( c_j \)'s become

\[
\sum_i \alpha'_i = \sum_j \beta'_j = \sum_i \sqrt{\alpha_i} r_i + \sum_j \sqrt{\beta_j} c_j = 0,
\] (77)

\[
\sum_i \frac{R'_i}{R_i} - \sum_j \frac{C'_j}{C_j} = \sum_i \sqrt{\alpha_i} r_i - \sum_j \sqrt{\beta_j} c_j = 0.
\] (78)

We give more detail on the derivation of (77) below. We have

\[
\sum_i \alpha'_i = \sum_i \frac{\alpha_i}{\alpha_i} \alpha'_i = \sum_i \alpha_i \left( \frac{R'_i}{R_i} + \sum_j B_{ij} C'_j \right) = \sum_i r_i \sqrt{\alpha_i} + \sum_i \sum_j B_{ij} R_i C'_j
\]

\[
= \sum_i r_i \sqrt{\alpha_i} + \sum_j \frac{c_j}{\beta_j} \sum_i B_{ij} R_i C_j = \sum_i r_i \sqrt{\alpha_i} + \sum_j c_j \sqrt{\beta_j},
\]

the derivation for \( \sum_j \beta'_j \) is analogous.

\[\square\]

### 3.4.2 Attractive fixpoints of tree recursions

The variables \( R_i, C_j, \alpha_i, \beta_j \) in this section refer to a priori different quantities as the variables in Section 3.4.1. We feel that this conflict is justified since we will establish that they coincide.

For convenience we repeat the tree recursions as stated in the introduction:

\[
\hat{R}_i \propto \left( \sum_{j=1}^q B_{ij} C_j \right)^{\Delta^{-1}} \quad \text{and} \quad \hat{C}_j \propto \left( \sum_{i=1}^q B_{ij} R_i \right)^{\Delta^{-1}}.
\] (8)

We are interested in the **fixpoints** of the tree recursions, that is, \( R_i \)'s and \( C_j \)'s such that

\[
\hat{R}_i \propto R_i \quad \text{and} \quad \hat{C}_j \propto C_j
\]

for all \( i, j \in [q] \). Note that the fixpoints correspond to the critical points of \( \Psi_1 \) (using Theorem 5)).

Next we examine the stability of fixpoints. For a continuously differentiable map a sufficient condition for a fixpoint to be attractive is if the spectral radius of the derivative is less than one at the fixpoint. We will use the following terminology for fixpoints whose attractiveness is established using this method.
Definition 9. A fixpoint $x$ of a function $f : M \to M$ is called **jacobian attractive fixpoint** if the Jacobian of $f$ at $x$ has spectral radius less than 1.

Lemma 30. Let $(r, c)$ be a fixpoint of the tree recursions. Let $\alpha_i = \sum_{j=1}^{q} B_{ij} R_i C_j$ and $\beta_j = \sum_{i=1}^{q} B_{ij} R_i C_j$ and let $L$ be the (matrix of the) map defined by (74). We have that $(r, c)$ is jacobian attractive if and only if $(\Delta - 1)L$ has spectral radius less than 1 in the subspace of $w = (r_1, \ldots, r_q, c_1, \ldots, c_q)$ that satisfy

$$\sum_{i=1}^{q} \sqrt{\alpha_i} r_i = 0 \quad \text{and} \quad \sum_{j=1}^{q} \sqrt{\beta_j} c_j = 0. \quad (75)$$

Proof. W.l.o.g. we can assume that $(r, c)$ is scaled so that

$$\sum_{i=1}^{q} \sum_{j=1}^{q} B_{ij} R_i C_j = 1. \quad (79)$$

Note that the scaling does not affect the value of $L$ nor does it affect the constraint (75).

When we perturb the $R_i$'s and $C_j$'s and apply one step of the tree recursion we obtain

$$\frac{\hat{R}'_i}{R_i} = (\Delta - 1) \frac{\sum_{j=1}^{q} B_{ij} R_i C_j C'_j}{\sum_{j=1}^{q} B_{ij} C_j} \quad \text{and} \quad \frac{\hat{C}'_j}{C_j} = (\Delta - 1) \frac{\sum_{i=1}^{q} B_{ij} R_i R'_i}{\sum_{i=1}^{q} B_{ij} R_i}. \quad (80)$$

We can rewrite (80) as follows

$$\frac{\hat{R}'_i}{R_i} = (\Delta - 1) \frac{\sum_{j=1}^{q} B_{ij} R_i C_j C'_j}{\alpha_i} \quad \text{and} \quad \frac{\hat{C}'_j}{C_j} = (\Delta - 1) \frac{\sum_{i=1}^{q} B_{ij} R_i R'_i}{\beta_j}. \quad (81)$$

The perturbation that scales all $R_i$'s by the same factor does not change the messages (since they are in the projective space) and hence we need to exclude it when studying local stability of (80). Similarly scaling all $C_j$'s by the same factor does not change the messages. We need to locate an invariant subspace of (81) whose complement corresponds to the scaling. We obtain the following subspace (it corresponds to preserving (79)):

$$\sum_{i=1}^{q} \alpha_i R'_i = 0 \quad \text{and} \quad \sum_{j=1}^{q} \beta_j C'_j = 0. \quad (82)$$

Now we check that (82) is invariant under the map (81), indeed,

$$\sum_{i=1}^{q} \alpha_i R'_i = (\Delta - 1) \sum_{i=1}^{q} \sum_{j=1}^{q} B_{ij} R_i C_j C'_j \quad \text{and} \quad \sum_{j=1}^{q} \beta_j C'_j = (\Delta - 1) \sum_{j=1}^{q} \beta_j C'_j = 0; \quad (83)$$

70
the argument for $\sum_{j=1}^{q} \beta_j \frac{\hat{C}_j}{C_j} = 0$ is analogous.

A fixpoint $(R_1, \ldots, R_q, C_1, \ldots, C_q)$ is Jacobian attractive if the linear transformation

\[
\left( \frac{R'_1}{R_1}, \ldots, \frac{R'_q}{R_q}, \frac{C'_1}{C_1}, \ldots, \frac{C'_q}{C_q} \right) \mapsto \left( \frac{\hat{R}'_1}{R_1}, \ldots, \frac{\hat{R}'_q}{R_q}, \frac{\hat{C}'_1}{C_1}, \ldots, \frac{\hat{C}'_q}{C_q} \right)
\]

given by (80) has spectral radius less than 1 in the subspace defined by (82).

Let $r_i = \sqrt{\alpha_i R'_i/R_i}$, $c_j = \sqrt{\beta_j C'_j/C_j}$, $\hat{r}_i = \sqrt{\alpha_i \hat{R}'_i/\hat{R}_i}$, and $\hat{c}_j = \sqrt{\beta_j \hat{C}'_j/\hat{C}_j}$. This linear transformation of variables turns (81) into

\[
\hat{r}_i = (\Delta - 1) \sum_{j=1}^{q} \frac{B_{ij} R_i C_j}{\sqrt{\alpha_i \beta_j}} c_j \quad \text{and} \quad \hat{c}_j = (\Delta - 1) \sum_{i=1}^{q} \frac{B_{ij} R_i C_j}{\sqrt{\alpha_i \beta_j}} r_i. \tag{84}
\]

Note that (84) is $(\Delta - 1)J$ where $J$ is the map defined by (74). The constraint (82) becomes (75).

### 3.4.3 Connecting attractive fixpoints to maximum entropy configurations

Now we are ready to prove Theorem 2.

**Proof of Theorem 2.** Let $S$ be the linear subspace defined by (75) (note that (77) together with (78) define the same subspace). The constraint for the fixpoint to be jacobian attractive is that $(\Delta - 1)L$ on $S$ has spectral radius less than 1. The constraint for the critical point to be Hessian maximum is that the eigenvalues of $(I + L)((\Delta - 1)L - I)$ on $S$ are negative (see equation (76)).

Note that $L$ is symmetric and it is a result of tensor product with the matrix $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$. Hence $L$ has symmetric real spectrum (symmetry means that if $a$ is an eigenvalue then so is $-a$). Note that $S$ is invariant under $L$ and hence the spectrum of $L$ on $S$ is a subset of the spectrum of $L$ (it is still symmetric real; the restriction wiped out a pair of eigenvalues $-1$ and 1).

The constraint for the fixpoint to be jacobian attractive, in terms of eigenvalues, is: for each eigenvalue $x$ of $L$ on $S$

\[
-1 < (\Delta - 1)x < 1. \tag{85}
\]

The constraint for the critical point to be Hessian maximum, in terms of eigenvalues, is:
for each eigenvalue $x$ of $L$ on $S$

$$(1 + x)((\Delta - 1)x - 1) < 0 \quad \text{and} \quad (1 - x)(- (\Delta - 1)x - 1) < 0,$$  \hspace{1cm} (86)

where the second constraint comes from the symmetry of the spectrum (thus $-x$ is an eigenvalue). Note that conditions (85) and (86) are equivalent (since $(1 + x)((\Delta - 1)x - 1)$ is negative for $-1 < x < 1/(\Delta - 1)$).
CHAPTER IV

THE GADGET

In this chapter, we construct the gadget which will be used in our NP-hardness results. The section is then devoted to analyzing the properties of the gadget.

The gadget is a random graph from a graph distribution $G_{r,n,\Delta}$, which closely resembles the graph distribution $G_{n,\Delta}$. The main difference is that $G_{r,n}$ is supported on bipartite graphs whose vertices have degrees both $\Delta$ and $\Delta - 1$, with $r$ controlling the number of vertices with degree $\Delta - 1$. The vertices of degree $\Delta - 1$ will be crucial to allow us to make connections between the gadgets without exceeding the degree bound $\Delta$.

We will study the random graph distribution $G_{r,n,\Delta}$ for sufficiently small values of $r$, allowing us to directly transfer the results from our analysis for the random graph distribution $G_{n,\Delta}$. In particular, the asymptotics of the first and second moments of the partition function for the two graph distributions will be essentially the same up to easily computable correction factors.

4.1 Construction

For $\Delta \geq 3$ and integers $n, r$ satisfying $n > r > 0$, we next describe the graph distribution $G_{r,n} := G_{r,n,\Delta}$.

1. $G_{r,n}$ is supported on bipartite graphs. The two parts of the bipartite graph are denoted by $+$, $-$ and each is partitioned as $U^s \cup W^s$ where $|U^s| = n$, $|W^s| = r$ for $s = \{+, -\}$. $U$ denotes the set $U^+ \cup U^-$ and similarly $W$ denotes the set $W^+ \cup W^-$. 

2. To sample $G \sim G_{r,n}$, sample uniformly and independently $\Delta$ matchings: (i) $(\Delta - 1)$ perfect matchings between $U^+ \cup W^+$ and $U^- \cup W^-$, (ii) a $n$-matching between $U^+$ and $U^-$. The edge set of $G$ is the union of the $\Delta$ matchings. Thus, vertices in $U$ have degree $\Delta$, while vertices in $W$ have degree $\Delta - 1$. 

73
The case \( r = 0 \) will also be critical for our arguments, in which case there are no vertices of degree \( \Delta - 1 \) and hence the graph distribution is identical to the distribution \( G_n := G_{n,\Delta} \), which we studied thoroughly in Chapters 2 & 3.

Let \( G \sim G_n^r \) and denote by \( \mu_G \) the Gibbs distribution on \( G \) with interaction matrix \( \mathbf{B} \). We let \( Q \) denote the set of dominant phases on a random \( \Delta \)-regular bipartite graph, that is, the union of the pairs \((\alpha, \beta)\) which maximize \( \Psi_{\mathbf{B}}^1(\alpha, \beta) \) (recall that \( \alpha, \beta \) are \( q \)-dimensional probability vectors, i.e., \( \alpha, \beta \in \triangle_q \) where \( \triangle_q \) is the standard \( (q-1) \)-simplex). We will use \( p \) to denote a dominant phase \((\alpha, \beta)\) and for the purposes of this section \( p^+, p^- \) will be used to denote the vectors \( \alpha, \beta \).

For a configuration \( \sigma : U \cup W \to [q] \), the footprint of \( \sigma \) is defined as a pair of \( q \)-dimensional probability vectors \((p^+_{\sigma}, p^-_{\sigma})\), i.e., \( p^+_{\sigma}, p^-_{\sigma} \in \triangle_q \). The vectors \( p^+_{\sigma}, p^-_{\sigma} \) count the frequencies of the colors in \( \sigma \) in the parts \( U^+, U^- \). Formally, for \( s \in \{+, -\} \), the \( i \)-th entry of \( p^s_{\sigma} \) is equal to \( |\sigma^{-1}(i) \cap U^s|/n \). The phase of a configuration \( \sigma \) is denoted by \( Y(\sigma) \) and is equal to

\[
Y(\sigma) := \arg \min_{p \in Q} \| p^+_{\sigma} - p^+ \|_1 + \| p^-_{\sigma} - p^- \|_1. \tag{87}
\]

If there are more than one dominant phases that achieve the minimum in (87), any tie breaking criterion may be used, say the lowest indexed phase. Note that the phase of \( \sigma \) depends only on the spins of vertices in \( U \). For \( \sigma : U \cup W \to [q] \), denote by \( \sigma_W \) the restriction of \( \sigma \) to vertices in \( W \).

The exact marginal distribution of \( \mu_G \) on the vertices in \( W \) is quite intricate. However, we shall display shortly that, given the phase of the configuration, it can be well approximated by an appropriate product measure. To do this, recall that every dominant phase \( p \in Q \) corresponds to a fixpoint of the tree recurrences (8). Let \((\hat{R}_1, \ldots, \hat{R}_q, \hat{C}_1, \ldots, \hat{C}_q)\) be a scaled version of \((R_1, \ldots, R_q, C_1, \ldots, C_q)\) so that \( \sum_i \hat{R}_i = 1 \) and \( \sum_i \hat{C}_i = 1 \). To avoid overloading the notation, we do not explicitly index the \( R_i \)'s and \( C_j \)'s by the phase \( p \).

Define the product measure \( \nu^\otimes_p(\cdot) \) on the space of spin assignments to vertices in \( W \). For \( \sigma : W \to [q] \) and \( p \in Q \), let

\[
\nu^\otimes_p(\sigma) = \prod_{i \in [q]} (\hat{R}_i)|_{\sigma^{-1}(i) \cap W^+}| \prod_{j \in [q]} (\hat{C}_j)|_{\sigma^{-1}(j) \cap W^-}. \tag{88}
\]
We can now state formally the properties of the gadget $G \sim G_n^r$ that we will need. We will need the following hypotheses for the spin system specified by $B$:

(H1) $B$ is regular and ergodic (irreducible and aperiodic).

(H2) Every dominant phase $p \in Q$ is a Hessian maximum of $\Psi^B_1(\alpha, \beta)$. Equivalently, by Theorem 2, the fixpoint of the tree recursions (8) corresponding to each $p \in Q$ is Jacobian stable (note that the validity of this assumption is allowed to vary with the degree $\Delta$).

The hypothesis (H1) allows to apply in full strength the results of Chapter 3. The hypothesis (H2) allows to compute the asymptotics of the moments using Laplace’s method. We will prove the following theorem in Section 4.2.

**Theorem 31.** Suppose that the interaction matrix $B$ satisfies hypotheses (H1) and (H2). Let $r$ be a fixed constant. Then, for every $\varepsilon > 0$, a random graph $G \sim G_n^r$ satisfies with probability $1 - o(1)$ as $n \to \infty$ all of the following:

1. For each $p \in Q$, $(1 - \varepsilon)/|Q| \leq \mu_G(Y(\sigma) = p) \leq (1 + \varepsilon)/|Q|$. That is, the phases in $Q$ appear with roughly equal probability.

2. For each $p \in Q$, for all $\eta : W \to [q]$, $\mu_G(\sigma_W = \eta | Y(\sigma) = p) / \nu_p^\otimes(\eta) \in [1 - \varepsilon, 1 + \varepsilon]$. That is, conditioned on the phase $p$ of the configuration, the spins of the vertices in $W$ are roughly independent and the marginal measure on them can be approximated by the measure $\nu_p^\otimes(\cdot)$.

3. There is no edge between $W^+$ and $W^-$. Moreover, there is no vertex in $G$ which has two neighbors in $W^+ \cup W^-$. Moreover, $G$ is simple with asymptotically positive probability and the above continue to hold with probability $1 - o(1)$ conditioned on $G$ being simple.

**Remark 8.** When $r$ is allowed to vary moderately with $n$, say $r = o(n^{1/4})$, Items 1 and 3 still hold, however Item 2 is no longer true. The reason is that the number of configurations $\eta$ grows with $n$, which does not allow to conclude Item 2 pointwise, i.e., for every $\eta : W \to [q]$. 

75
Instead, one needs to weaken Item 2 to the following statement. For every $\varepsilon > 0$, for every $p \in \mathcal{Q}$,

$$\lim_{n \to \infty} \sup_{\eta \in [q]^W} \Pr_{G_n^r} \left( \frac{\mu_G(\sigma_W = \eta | Y(\sigma) = p)}{\nu_p(\eta)} \notin (1 \pm \varepsilon) \right) = 0. \quad (89)$$

This version will only be used for the AP-reductions in Chapter 7, where we do need $r$ to vary with $n$. We will comment where needed how the proofs should be (slightly) modified to obtain (89).

### 4.2 Proving the Properties of the Gadget

The goal of this section is to give the proof of Theorem 31. To be able to conclude (89) in the case that $r$ varies moderately with $n$, we will work under the slightly weaker assumption $r = o(n^{1/4})$.

Let $G \sim G_n^r$. To get a handle on Items 1 and 2 of Theorem 31, we first define the partitioned functions conditioned on a phase $p \in \mathcal{Q}$. Similar definitions appear in [49]. For a configuration $\eta : W \to [q]$ and $\alpha, \beta \in \Delta_q$, define

$$Z^G_{\alpha,\beta}(\eta) = \sum_{\sigma : \sigma_W = \eta, (p^+, p^-) = (\alpha, \beta)} w_G(\sigma), \quad Z^p_G(\eta) = \sum_{\alpha, \beta : p = \arg \min_{p'} \| (\alpha, \beta) - (p^+, p^-) \|} Z^\alpha\beta_G(\eta), \quad Z_G = \sum_{\eta} Z^\alpha\beta_G(\eta). \quad (90)$$

Let us explain briefly these definitions. $Z^\alpha\beta_G(\eta)$ is the contribution from configurations which agree with $\eta$ on $W$ and their footprint on $U$ is $(\alpha, \beta)$. To picture the definition of $Z^p_G(\eta)$, view the phases $\mathcal{Q}$ as modes in the Gibbs distribution which “attract” the configurations closest to them. Note that distances here are only with respect to the spin assignments on $U$. Therefore, the spin assignment on $W$ induces a partition on the attraction space of the phase $p$. In this view, $Z^p_G(\eta)$ is simply the contribution of the set indexed by $\eta$ in the partition. Finally, $Z^p_G$ is the total contribution of the configurations which are attracted by $p$.

The following equalities display the relevance of these quantities to Theorem 31.

$$\mu_G(Y(\sigma) = p) = \frac{Z^p_G}{\sum_{p \in \mathcal{Q}} Z^p_G}, \quad \mu_G(\sigma_W = \eta | Y(\sigma) = p) = \frac{Z_G^\alpha\beta(\eta)}{Z_G^p}. \quad (91)$$

It will also be useful to explicitly state how the definitions in (92) degenerate in the case $r = 0$. In this setting there are no vertices of degree $\Delta - 1$ (and hence no set $W$), so
the graph distribution $G_n^0$ is identical to the graph distribution $G(n, \Delta)$. The definitions in (90) extend to this setting by simply dropping the argument $\eta$. The conditioned partition functions when $r = 0$ are thus given by

$$Z^\alpha_\beta = \sum_{(p^+, p^-) = (\alpha, \beta)} w_G(\sigma), \quad Z^p = \sum_{p = \arg\min_{p'} \| (\alpha, \beta) - (p^+, p^-) \|}$$

(92)

To start, we are going to show that Items 1 and 2 of Theorem 31 hold in expectation. This is the scope of the following lemma. Note that $o(1)$ refers to quantities that tend to 0 as $n \to \infty$.

**Lemma 32.** Let $r$ be a fixed constant and let $p$ be a phase, i.e., $p \in Q$. There exists a constant $C(p)$ such that for every $\eta: W \to [q]$, it holds that

$$\mathbb{E}^p_{G_n}[Z^p_G(\eta)] = (1 + o(1)) C' \nu_p^\otimes(\eta) \mathbb{E}^0_{G_n}[Z^p_G], \quad \text{and thus} \quad \sup_{\eta} \frac{\mathbb{E}^p_{G_n}[Z^p_G(\eta)]}{\mathbb{E}^0_{G_n}[Z^p_G]} - \nu_p^\otimes(\eta) = o(1).$$

(93)

Moreover, when the phases $Q$ are permutation symmetric, $\mathbb{E}^p_{G_n}[Z^p_G] = (1 + o(1)) \mathbb{E}^0_{G_n}[Z^p_G]$ for any phases $p, p' \in Q$ and the constant $C$ in (93) does not depend on the particular phase $p$. Consequently, for $p, p' \in Q$

$$\mathbb{E}^p_{G_n}[Z^p_G] = (1 + o(1)) C'' \mathbb{E}^0_{G_n}[Z^p_G], \quad \text{and thus} \quad \frac{\mathbb{E}^p_{G_n}[Z^p_G]}{\sum_{p' \in Q} \mathbb{E}^0_{G_n}[Z^{p'}_G]} = (1 + o(1)) \frac{1}{|Q|}. \quad (94)$$

Proof. The second equalities in each of (93) and (94) follow immediately from the first. The latter may be proved by explicit calculations following the same arguments as in [49, Lemma 3.3] and essentially reduce to arguing that certain sums are dominated by their maximum terms.

It is worthy to note that the first part of the lemma is true even if the phases are not permutation symmetric, which is not necessarily true for the second part.

In light of Equations (91), (93) and (94), the path to obtain Items 1 and 2 of Theorem 31 is now paved: it suffices to show that the conditioned partition functions $Z^p_G(\eta)$ are (with positive probability) arbitrarily close to their expectations for large $n$. Note that we want this to be simultaneously true for all $p$ and $\eta$, that is, for the same graph $G$. This in turn
requires using in full strength a theorem by Janson [25], which is an extension of the small
subgraph conditioning method introduced by Robinson and Wormald [46].

We do a quite extensive, and hopefully illuminating, exposition of these theorems and
their application in our setting in the next section. For satisfying the reader who is more
interested in the proof of Theorem 31, the following lemma is a stripped-down version of
the results in Section 2.3, yet at the same point containing some important bits which will
allow us to motivate it. Note that we have already discussed a special case of the following
lemma, cf. Lemma 33 in Section 1.3.3. Note that the latter is obtained by setting \( r = 0 \)
and replacing the random variables \( Z_P^G \) with \( Z_G^{\alpha,\beta} \).

**Lemma 33.** Let \( r \geq 0 \) be a constant not depending on \( n \). Let \( G \sim G_n^r \) and denote by \( X_{\eta,i} \),
\( i = 1, 2, \ldots \), the number of cycles of length \( 2i \) in \( G \). There exist random variables \( W_{\eta,i}^P \), a
deterministic function of \( X_{\eta,1}, X_{\eta,2}, \ldots, X_{\eta,i} \), such that for every \( \varepsilon > 0 \)
\[
\lim_{m \to \infty} \limsup_{n \to \infty} \Pr_{G_n^r} \left( \bigcup_{\eta} \left[ \frac{Z_P^G(\eta)}{E_{G_n^r}[Z_P^G(\eta)]} - W_{\eta,i}^P \right] > \varepsilon \right) = 0, \tag{95}
\]
There also exists a positive constant \( c > 0 \) such that \( W_{\eta,i}^P > c \) uniformly in \( m, n \). Moreover,
when the phases \( Q \) are permutation symmetric, the variables \( W_{\eta,i}^P \) do not depend on the
phase \( \eta \).

**Remark 9.** When \( r \) is allowed to vary with \( n \), say \( r = o(n^{1/4}) \), (95) must be modified into
\[
\lim_{m \to \infty} \limsup_{n \to \infty} \Pr_{G_n^r} \left( \left[ \frac{Z_P^G(\eta)}{E_{G_n^r}[Z_P^G(\eta)]} - W_{\eta,i}^P \right] > \varepsilon \right) = 0. \tag{96}
\]

Lemma 33 provides a straightforward proof of Theorem 31, so we shall elucidate its most
important aspects in an attempt to demystify its rather unintuitive statement. Equation
(95) says that for all sufficiently large \( m, n \) the random variables \( Z_P^G(\eta)/E_{G_n^r}[Z_P^G(\eta)] \) are
well-approximated by the variables \( W_{\eta,i}^P \), with large probability. To get a feeling about this
statement, it is well known fact that a random \( \Delta \)-regular graph is locally tree-like and its
girth diverges as \( n \to \infty \). That is, as \( n \) grows large, for any positive integer \( t \), for all but
\( o(n) \) vertices, the \( t \)-depth neighborhood of a vertex is eventually isomorphic to the first \( t \)
levels of the infinite \( \Delta \)-regular tree. This is in alignment with the fact that \( E_{G_n^r}[Z_P^G(\eta)] \) is
determined by the Gibbs measure on the infinite \( \Delta \)-regular tree associated to the phase \( \eta \).
On the other hand, a graph $G \sim \mathcal{G}_n^r$ does have $o(n)$ vertices which are contained in constant sized cycles. Thus, it is reasonable to expect that $Z^p_G(\eta)$ fluctuates from its expectation. It is equally reasonable to expect the fluctuations to depend on the presence of small cycles which occur with small but non-zero probability.

The surprising aspect of (95), a consequence of applying the conditioning method, is that there is an explicit handle on these fluctuations, a crucial component in the proof of Theorem 31. This handle is given by the variables $W^p_{mn}$, which are a deterministic function of the small cycle counts in $G$. Crucially for our proof of Theorem 31, when the phases are permutation symmetric, the fluctuations from the expectation are captured by a single random variable, which allows us to control them uniformly over all the phases $p$ and configurations $\eta$.

We should point out that the notation $W^p_{mn}$ should not be confused by any means to the labeling of the degree $\Delta - 1$ vertices in $G$, i.e., the set of vertices $W$.

Proof of Theorem 31. We consider first the case that $r$ is fixed, and then discuss how to modify the argument for $r = o(n^{1/4})$. Let $\varepsilon' > 0$ be sufficiently smaller than $\varepsilon$, to be picked later, and consider also an arbitrary $\varepsilon'' > 0$.

By Lemma 33, for all $m,n$ sufficiently large the random variables $Z^p_G(\eta)/\mathbb{E}_{\mathcal{G}_n^r}[Z^p_G(\eta)]$ are well approximated by $W^p_{mn}$ with large probability. That is, there exist $M(\varepsilon'')$, $N(\varepsilon'')$ such that for $m \geq M$ and $n \geq N$, it holds with probability $1 - \varepsilon''$ over the choice of the graph $G$ that, for every phase $p$ and every configuration $\eta : W \rightarrow [q]$,

$$Z^p_G(\eta) = (W^p_{mn} \pm \varepsilon')\mathbb{E}_{\mathcal{G}_n^r}[Z^p_G(\eta)].$$

We will show that whenever this is the case (for an appropriate choice of $\varepsilon'$), Items 1 and 2 hold. To do this, sum (97) over $\eta$ to obtain that for each phase $p$, it holds

$$Z^p_G = (W^p_{mn} \pm \varepsilon')\mathbb{E}_{\mathcal{G}_n^r}[Z^p_G],$$

Using that $W^p_{mn}$ are uniformly bounded by the positive constant $c$ in Lemma 33, we obtain that for $\varepsilon'$ sufficiently smaller than $c$, the ratio $Z^p_G(\eta)/Z^p_G$ is within a multiplicative $(1 \pm \varepsilon)$ from $\mathbb{E}_{\mathcal{G}_n^r}[Z^p_G(\eta)]/\mathbb{E}_{\mathcal{G}_n^r}[Z^p_G]$. This gives Item 2 of the theorem, when used in conjunction
with (91) and (94). Note that this part of the argument did not use that the phases $\mathbf{p}$ are permutation symmetric.

To obtain Item 1, we have to use that the phases $\mathbf{p}$ are permutation symmetric. Then $W^{\mathbf{p}}_{mn} =: W_{mn}$ by the last assertion in Lemma 33. Thus, a summation of (98) over $\mathbf{p} \in \mathcal{Q}$ gives $Z^\mathbf{p}_G = (W_{mn} \pm \varepsilon')E_{G}|_{[Z^\mathbf{p}_G]}$. Exactly the same reasoning yields the thesis.

It is a standard union bound to show that Item 3 holds with probability $1 - o(1)$ over the choice of the graph $G$, essentially because $G$ is an expander. Perhaps the second assertion there requires a brief proof sketch. Let $v \in U^+ \cup W^+$, $w_1, w_2 \in W^-$ and let $E_i$ be the event that $(v, w_i)$ is an edge of $G$. The events $E_1, E_2$ are negatively correlated since $v$ has a fixed number of edges incident to it, either $\Delta$ or $\Delta - 1$. It is also easy to see that $\Pr_{G_n}(E_i) \leq 1 - (1 - 1/n)^\Delta = O(1/n)$, so that $\Pr_{G_n}(E_1 \cap E_2) = O(1/n^2)$. A union bound over the roughly $n v^2 = o(n^2)$ choices for the vertices $v, w_1, w_2$ gives the desired bound.

Thus, a graph $G \sim G_n^r$ satisfies Items 1, 2 and 3 with probability $1 - \varepsilon''$ for all sufficiently large $n$. Since $\varepsilon''$ was arbitrary, this gives the first part of the theorem. The second part of the theorem follows immediately by contiguity, see [25, Section 2].

4.2.1 Application of the Small Graph Conditioning Method

The application of Theorem 17, and similarly Lemma 18, requires a verification of its assumptions. This check is routine for the most part, but it is nevertheless technically arduous, mainly because of condition (A3), which requires precise calculation of the moments’ asymptotics. We suppress the verification in the following lemma whose proof is given later in this section. The lemma includes some details on a few quantities which will be relevant in the proof of Lemma 33.

**Lemma 34.** Let $G \sim G_n^r$ and $X_{in}$ be the number of cycles of length $2i$ appearing in $G$, $i = 1, 2, \ldots$. Let $S = \{(\mathbf{p}, \eta) | \mathbf{p} \in \mathcal{Q}, \eta : W \to [q]\}$ and for $s \in S$ with $s = (\mathbf{p}, \eta)$, set $Y_n(s) = Z^\mathbf{p}_G(\eta)$. In the setting of Theorem 14, the assumptions of Theorem 17 hold.

Further, for $s \in S$ with $s = (\mathbf{p}, \eta)$, for $i = 1, 2, \ldots$, $\delta_i(s)$ satisfies (i) $\delta_i(s) > 0$, (ii) $\delta_i(s)$ depends on $\mathbf{p}$ but not on $\eta$, (iii) $\sum_i \lambda_i \delta_i(s) < \infty$, (iv) if the phases are permutation
symmetric, $\delta_i^{(s)}$ depends on the spin model but not on the particular phase $p$.

Further, all of the above hold if $S = \{(p, \eta) \mid p \in \mathcal{Q}, \eta : W \to [q]\}$ and $Y_n^{(s)} = Z_G^{\alpha, \beta}(\eta)$.

Using Lemmas 18 and 34, we are ready to prove Lemmas 6 and 33.

Proof of Lemmas 6 and 33. To see (14) and (95), note that the $W_{mn}^{(s)}$ of Lemma 18 depend on the particular $s$ only through $\delta_i^{(s)}$. By Item (ii) of Lemma 34, these depend only on $p$ in general and specifically for the permutation symmetric case, only on the spin model by Item (iv).

It remains to prove that $W_{mn}^p$ are lower bounded uniformly in $p$ by a positive constant. Since the number of phases $p$ is bounded by a constant depending only on the spin model, it suffices to show that this is the case for a fixed phase $p$. Using Item (i) of Lemma 34 and that the random variables $X_{in}$ are non-negative integer valued, we have everywhere the bound

$$W_{mn}^p = \prod_{i=1}^m \left(1 + \delta_i^p\right)^{X_{in}} \exp\left(-\lambda_i \delta_i^p\right) \geq \prod_{i=1}^m \exp\left(-\lambda_i \delta_i^p\right) > \prod_{i=1}^\infty \exp\left(-\lambda_i \delta_i^p\right).$$

Note that we have identified the $\delta_i^{(s)}$'s with the respective $\delta_i^p$'s, this is justified by Item (ii) of Lemma 34. The last quantity is finite and positive by Item (iii) in Lemma 34. □

We next prove Lemma 34 which amounts to checking the validity of the assumptions (A1)-(A4) of Theorem 17 for $Z_G^p(\eta)$ for every phase $p$ and configuration $\eta : W \to [q]$. Recall that a phase $p$ corresponds to a pair of vectors $(\alpha, \beta)$ which is a global maximum of $\Phi$, which in turn corresponds to a triple $(\alpha, \beta, x)$, a global maximum of $\Upsilon_1$, see Section 2.2.1 for details. We shall also check the validity of the assumptions for the random variables $Z_G^{\alpha, \beta}$ when $G \sim \mathcal{G}_{n, \Delta}$. This will make the arguments crispier and easier to extend to the slightly more peculiar random variables $Z_G^p(\eta)$.

To begin, the following lemma puts together some relevant quantities and information which have appeared in Section 3.4. For vectors $z_i \in \mathbb{R}^{m_i}, i = 1, \ldots, t$ we denote by $[z_1, \ldots, z_t]^\top$ the vector which is the concatenation of the vectors $z_1, \ldots, z_t$. For a vector $z = [z_1, \ldots, z_n]^\top$ and a function $f : \mathbb{R} \to \mathbb{R}$, we denote by $f(z)$ the vector $[f(z_1), \ldots, f(z_n)]^\top$, provided that the $f(z_i)$'s are well defined.
Lemma 35. Suppose that \((\alpha, \beta)\) is a Hessian local maximum of \(\Psi_1\) and let \(p\) be the phase corresponding to the pair \((\alpha, \beta)\). Define the vector \(x = (x_{ij})_{i,j \in [q]}\) as in Lemma 20.

Let \(J\) be the matrix
\[
\begin{bmatrix}
0 & L \\
L^\top & 0
\end{bmatrix}
\]
where \(L\) is the \(q \times q\) matrix whose \(ij\)-entry is given by \(x_{ij}/\sqrt{\alpha_i \beta_j}\). It holds that:

1. The spectrum of \(J\) is
\[
\pm 1, \pm \lambda_1, \ldots, \pm \lambda_{q-1},
\]
where the \(\lambda_i\)'s are positive and satisfy \(\max_i \lambda_i < \frac{1}{\Delta - 1}\).

2. The eigenspaces of \(J\) associated to the (simple) eigenvalues \(\pm 1\) are given by \([\sqrt{\alpha}, \pm \sqrt{\beta}]^\top\).

Moreover, any other eigenvector of \(J\) is of the form \([v_1, v_2]^\top\), where \(\sqrt{\alpha}^\top v_1 = \sqrt{\beta}^\top v_2 = 0\).

Relevant to Lemma 34, observe that if the phases \(p\) are permutation symmetric, then the \(\lambda_i\)'s are common for all phases.

Recall that \(Z_G^{\alpha, \beta}\) is the weight of configurations in \(\Sigma^{\alpha, \beta}\) for a random \(\Delta\)-regular bipartite graph \(G \sim \mathcal{G}_{n,\Delta}\). Let \(X_i\) be the number of cycles of even length \(i\) in \(G\). We have the following lemmas.

Note that we prefer to reserve the notation \(\lambda_i\) for the eigenvalues of the matrix \(J\) of Lemma 35, so that we make the slight change of notation in Theorem 17 from \(\lambda_i\) to \(\mu_i\); no confusion should arise.

Lemma 36 (Lemma 7.3 in [43]). Condition 1 of Theorem 17 holds for even \(i\) with
\[
\mu_i = \frac{r(\Delta, i)}{i} = \frac{(\Delta - 1)^i + (-1)^i(\Delta - 1)}{i},
\]
where \(r(\Delta, i)\) is the number of ways to properly edge color a cycle of length \(i\) with \(\Delta\) colors.

The proof of Lemma 36 is given in [43] and is omitted.

Lemma 37. In the notation and setting of Lemma 35, for every fixed \(r \geq 0\), every \(\eta : W \to [q]\) and even \(i \geq 2\), it holds that
\[
\frac{\mathbb{E}_G[Z_G^{\alpha, \beta} X_i]}{\mathbb{E}_G[Z_G^{\alpha, \beta}]} \rightarrow \frac{\mu_i(1 + \delta_i)}{\mathbb{E}_G[Z_G^{\alpha, \beta}]} \quad \text{as} \quad n \to \infty, \quad \text{where} \quad \delta_i = \sum_{j=1}^{q-1} \lambda_j^i. \quad (99)
\]
In particular, $\delta_i$ is positive.

The proof of Lemma 37 is given in Section 4.2.2.

**Lemma 38.** In the setting of Lemma 37, for every fixed $r \geq 0$, every $\eta : W \rightarrow [q]$ and for every finite sequence $m_1, \ldots, m_k$ of nonnegative integers, it holds that

$$\frac{E_G[Z_G^{\alpha,\beta}[X_2]_{m_1} \cdots [X_{2k}]_{m_k}]}{E_G[Z_G^{\alpha,\beta}]} \frac{E_{G^n}[Z_{G^n}^p(\eta)[X_2]_{m_1} \cdots [X_{2k}]_{m_k}]}{E_{G^n}[Z_{G^n}^p(\eta)]} \rightarrow \prod_{i=1}^k (\mu_i(1 + \delta_i))^{m_i} \text{ as } n \rightarrow \infty.$$

Once we give the proof of Lemma 37, the proof of Lemma 38 is identical to [43, Proof of Lemma 7.5] and is omitted.

**Lemma 39.** In the notation and setting of Lemma 35, it holds that

$$\exp \left( \sum_{\text{even } i \geq 2} \mu_i \delta_i^2 \right) = \prod_{i=1}^{q-1} \prod_{j=1}^{q-1} (1 - (\Delta - 1)^2 \lambda_i^2 \lambda_j^2)^{-1/2} \prod_{i=1}^{q-1} \prod_{j=1}^{q-1} (1 - \lambda_i^2 \lambda_j^2)^{-(\Delta-1)/2}.$$  

Moreover, $\sum_i \mu_i \delta_i < \infty$.

The proof of Lemma 39 is given in Section 4.2.2.

Finally, we find the asymptotics of the second moment over the first moment squared.

**Lemma 40.** In the notation and setting of Lemma 35, for every fixed $r \geq 0$, every $\eta : W \rightarrow [q]$, it holds that

$$\lim_{n \rightarrow \infty} \frac{E_G[(Z_G^{\alpha,\beta})^2]}{(E_G[Z_G^{\alpha,\beta}])^2} = \lim_{n \rightarrow \infty} \frac{E_{G^n}[(Z_{G^n}^p(\eta))^2]}{(E_{G^n}[Z_{G^n}^p(\eta)])^2} = \prod_{i=1}^{q-1} \prod_{j=1}^{q-1} (1 - (\Delta - 1)^2 \lambda_i^2 \lambda_j^2)^{-1/2} \prod_{i=1}^{q-1} \prod_{j=1}^{q-1} (1 - \lambda_i^2 \lambda_j^2)^{-(\Delta-1)/2}.$$  

The proof of Lemma 40 is quite extensive. In Section 4.3, we reduce the asymptotics to determinants of relevant Hessian matrices. These determinants are computed in Section 4.4.2, where also the proof of Lemma 40 is given.

It is easy to check that Lemmas 36 to 40 verify the assumptions (A1)-(A4) in Theorem 17 for the random variables $Z_G^{\alpha,\beta}$ when $G \sim \mathcal{G}(n, \Delta)$. We do not do this explicitly since we are more interested in the random variables $Z_{G^n}^p(\eta)$ when $G \sim \mathcal{G}_n^r$.
Proof of Lemma 34. Let $X_i$ be the number of cycles of even length $i$ in a graph $G \sim G_n^r$. Then assumption (A1) of Theorem 17 holds for even $i$ with the same $\lambda_i'$ as in Lemma 36, the proof being identical. Moreover, the analogous statement of Lemma 38 reads as
\[
\lim_{n \to \infty} \frac{E_{G_n^r}[Z_G^p(\eta) [X_2]_{m_1} \cdots [X_{2k}]_{m_k}]}{E_{G_n^r}[Z_G^p(\eta)]} = \prod_{i=1}^k (\mu_i(1 + \delta_i))^{m_i},
\]
where the $\delta_i$’s are the same as in Lemma 37. The proof of (100), as for Lemma 38, first argues about the analog of Lemma 37. To prove the latter, one first expands the sums and argues that only the maximum terms contribute in the limit. This is sufficient to prove
\[
\lim_{n \to \infty} \frac{E_{G_n^r}[Z_G^p(\eta) X_2]}{E_{G_n^r}[Z_G^p(\eta)]} = \lim_{n \to \infty} \frac{E_{G_n^r}[Z_G^{\alpha,\beta}(\eta) X_i]}{E_{G_n^r}[Z_G^{\alpha,\beta}(\eta)]}.
\]
The rhs can be treated as in [49, Lemma 3.8]. This way one obtains assumption (A2) of Theorem 17. Assumptions (A3) to (A4) then hold from combining Lemmas 39 and 40. This proves the first part of the lemma.

The second part, that is, Items (i) to (iv), follow from Lemmas 35, 37 and Equation (100). \hfill \square

4.2.2 Proofs

We now give the proofs of Lemmas 37 and 39 which are the most crucial components for the success of the method in our case.

Proof of Lemma 37. The proof is close to [43, Proof of Lemma 7.4], the approach is minorly different to account for the $q$-spin setting. We make the minor notation change from $X_i$ to $X_\ell$. We first give the proof for $Z_G^{\alpha,\beta}$ for $G \sim G_n$.

Let $S = \{S_1, \ldots, S_q\}$ and $T = \{T_1, \ldots, T_q\}$ be partitions of $V_1$ and $V_2$ respectively such that $|S_i| = \alpha_i n$ and $|T_j| = \beta_j n$ for all $i, j \in [q]$. Denote by $Y_{S,T}$ the weight of the configuration $\sigma$ that $S, T$ induce, i.e. for a vertex $v \in V_1$, $\sigma(v) = i$ iff $v \in S_i$ and similarly for vertices in $V_2$.

Fix a specific pair of $S, T$. By symmetry,
\[
\frac{E[Z_G^{\alpha,\beta} X_\ell]}{E[Z_G^{\alpha,\beta}]} = \frac{E[Y_{S,T} X_\ell]}{E[Y_{S,T}]}.
\]
We now decompose $X_\ell$ as follows:
• $\xi$ will denote a proper $\Delta$-edge colored, rooted and oriented $\ell$-cycle ($r(\Delta, \ell)$ possibilities), in which the vertices are colored with $\{Y_1, \ldots, Y_q, G_1, \ldots, G_q\}$ and edges are colored with $\{1, \ldots, \Delta\}$.

A vertex colored with $Y_i$ (resp. $G_i$) for some $i \in [q]$ will be loosely called yellow (resp. green) and signifies that the vertex belongs to $S_i$ (resp. $T_i$). Since a yellow vertex belongs to $V_1$, and a green vertex belongs to $V_2$, a vertex coloring is consistent with the bipartiteness of the random graph if adjacent vertices of the cycle are not both yellow or green, that is, the vertex assignments which are prohibited for neighboring vertices in the cycle are $(Y_i, Y_j)$ and $(G_i, G_j)$, $\forall (i, j) \in [q]^2$. Note here that we do not explicitly prohibit assignments $(Y_i, G_j)$ in the presence of a hard constraint $B_{ij} = 0$; this will be accounted otherwise. The color of the edges will prescribe which of the $\Delta$ perfect matchings an edge of a (potential) cycle will belong to.

• Given $\xi, \zeta$ denotes a position that an $i$-cycle can be, i.e., the exact vertices it traverses in order, such that the prescription of the vertex colors of $\xi$ is satisfied.

• $1_{\xi, \zeta}$ is the indicator function whether a cycle specified by $\xi, \zeta$ is present in the graph $G$.

Note that each possible cycle corresponds to exactly $2\ell$ different configurations $\xi$ (the number of ways to root and orient the cycle). For each of those $\xi$, the respective sets of configurations $\zeta$ are the same. Hence, we may write

$$X_\ell = \frac{1}{2\ell} \sum_\xi \sum_\zeta 1_{\xi, \zeta}.$$ 

Let $p_1 := \Pr[1_{\xi, \zeta} = 1]$. It follows that

$$\mathbb{E}[Y_S, T X_\ell] = \frac{1}{2\ell} \sum_\xi \sum_\zeta p_1 \cdot \mathbb{E}[Y_S, T|1_{\xi, \zeta} = 1].$$

In light of (101), we need to study the ratio $\mathbb{E}[Y_S, T|1_{\xi, \zeta} = 1]/\mathbb{E}[Y_S, T]$. At this point, to simplify notation, we may assume that $\xi, \zeta$ are fixed.

We have shown in Section 2.2.1 that

$$\mathbb{E}[Y_S, T] = \left( \sum_x \left[ \left( \frac{n}{x} \right)^{-1} \prod_i \left( \frac{\alpha_i n}{x_i[i] n} \right) \prod_j \left( \frac{\beta_j n}{x_{[j]}[j] n} \right) \prod_{i,j} B_{ij}^{x_{ij} n} \right] \right)^{\Delta}, \quad (102)$$

85
Thus, for the given $\xi$, we have

$$\sum_{i,j} a_{ij} = 2y_i, \sum_i a_{ij} = 2g_j, \sum_{i,j} a_{ij} = 2\ell.$$  \hfill (103)

We are almost set to compute $E[Y_{S,T}|1_{\xi,\zeta} = 1]$. For the $k$-th matching, denote by $x$ the total number of edges between sets $S_i$ and $T_j$ in the $k$-th matching. This number includes the $a_{ij}(k)$ edges prescribed by $\xi, \zeta$. Set $E = E[Y_{S,T}|1_{\xi,\zeta} = 1]$. We have

$$E = \prod_{k=1}^{\Delta} \left( \sum_x \left[ \left( \frac{(n-a(k))}{nx-a(k)} \right)^{-1} \prod_i \left( \frac{\alpha_in-a_{ij}(k)}{\alpha_{ij}(k)} \right) \prod_j \left( \frac{\beta_jn-a_{ij}(k)}{\beta_{ij}(k)} \right) \prod_{i,j} B_{ij}^{nx_{ij}} \right] \right),$$

where we remind the reader the notation $a_{ij} = (a_{ij}, \ldots, a_{ij})$ and $a_{ij} = (a_{ij}, \ldots, a_{ij})$.

Standard approximations of binomial coefficients, see for example [17, Lemma 27], give

$$\frac{(x_{ij} - a_{ij})}{x_{ij} \alpha_i a_{ij}} \sim \frac{\prod_j (x_{ij})^{a_{ij}(k)}}{\alpha_i a_{ij}}, \frac{(x_{ij} - a_{ij})}{x_{ij} \beta_j a_{ij}} \sim \frac{\prod_i (x_{ij})^{a_{ij}(k)}}{\beta_j a_{ij}}, \frac{(n-a(k))}{xn-a(k)} \sim \prod_{i,j} (x_{ij})^{a_{ij}(k)}.$$}

Thus, we obtain

$$\frac{E[Y_{S,T}|1_{\xi,\zeta} = 1]}{E[Y_{S,T}]} \sim \prod_{i,j} \frac{(x_{ij})^{a_{ij}}}{\sum_i \alpha_i a_{ij}} \prod_j \frac{\beta_j a_{ij}}{\sum_i a_{ij}}.$$

Clearly $p_1 \sim n^{-\ell}$ and for given $\xi$, the number of possible $\zeta$ is asymptotic to $n^\ell \prod_i \alpha_i^{y_i} \prod_j \beta_j^{y_j}$. Thus, for the given $\xi$, we have

$$\sum_{\xi,\zeta} p_1 E[Y_{S,T}|1_{\xi,\zeta} = 1] \sim \prod_{i} \alpha_i^{y_i} \prod_{j} \beta_j^{y_j} \prod_{i,j} (x_{ij})^{a_{ij}} \sum_{i,j} \frac{\alpha_i a_{ij}}{\prod_j \beta_j a_{ij} \sum_i a_{ij}} = \prod_{i,j} \left( \frac{x_{ij}}{\sqrt{\alpha_i \beta_j}} \right)^{a_{ij}} \prod_{i} \alpha_i^{y_i} \prod_{j} \beta_j^{y_j}.$$
Note that the rhs evaluates to 0 whenever there exist \( i, j \) such that \( B_{ij} = 0 \) but \( a_{ij} \neq 0 \), since then we have \( x_{ij} = 0 \). This is in complete accordance with the fact that the configuration induced by the partition \( \{S, T\} \) has zero weight. Thus, by (101), we may write

\[
\frac{E[YX_\ell]}{E[Y]} = r(\Delta, \ell) \cdot \frac{1}{2\ell} \cdot \sum_{\xi} N_a \left( \frac{x_{ij}}{\alpha_i \beta_j} \right)^{a_{ij}},
\]

where \( a = \{a_{11}, \ldots, a_{qq}\} \) and \( N_a \) is the number of possible \( \xi \) with \( a_{ij} \) edges having assignment \((Y_i, G_j)\). To analyze this sum, we employ a technique given in [25]. The idea is to define a weighted transition matrix and view it as a weighted graph. The powers of the matrix count the (multiplicative) weight of walks in the graph and a closed walk in this graph will correspond to a specification \( \xi \). By defining the weights appropriately, one can also ensure that each closed walk will correctly capture the weight of the specification \( \xi \).

In our setting, the transition matrix is simply the matrix \( J \) of Lemma 35. The first \( q \) rows and \( q \) columns correspond to the colors \( Y_i \) and the remaining rows and columns to colors \( G_j \). The total weight of closed walks of length \( \ell \) is given by \( \text{Tr}(J^\ell) \). Using the description of the eigenvalues given in Item 1 of Lemma 35, we obtain that for even \( \ell \),

\[
\text{Tr}(J^\ell) = 2 \left( 1 + \sum_{i=1}^{q-1} \lambda_i^\ell \right).
\]

This concludes the proof for the variables \( Z^{\alpha, \beta} \).

We next turn to the variables \( Z^{\alpha, \beta}_G(\eta) \) when \( G \sim G_n^r \). For a fixed \( \eta : W \to [q] \), our goal is to compute \( E_{G_n^r}[Z^{\alpha, \beta}_G(\eta) X_\ell]/E_{G_n^r}[Z^{\alpha, \beta}_G(\eta)] \). Denote by \( \eta^\pm \) the \( q \)-dimensional vectors whose \( i \)-th entries are given by \( |\sigma^{-1} \cap W^\pm| \) (thus \( \eta^+ \) is the analog of \( \alpha n \) and \( \eta^- \) is the analog of \( \beta n \)).

For \( x \in M_1(\alpha + \eta^+/n, \beta + \eta^-/n) \), let

\[
k_G^{\alpha, \beta, x}(\eta) := \left( \frac{n + r}{xn} \right)^{-1} \prod_i \left( \alpha_i n + \eta_i^+ \right) \prod_j \left( \beta_j n + \eta_j^- \right) \prod_{i,j} (B_{ij})^{nx_{ij}},
\]

and for \( x \in M_1(\alpha, \beta) \), let

\[
k_G^{\alpha, \beta, x} := \left( \frac{n}{xn} \right)^{-1} \prod_i \left( \alpha_i n \right) \prod_j \left( \beta_j n \right) \prod_{i,j} (B_{ij})^{nx_{ij}},
\]

We have that

\[
E_{G_n^r}[Z^{\alpha, \beta}_G(\eta)] = \sum_{\alpha, \beta} \left( \begin{array}{c} n \\ \alpha n \end{array} \right) \left( \begin{array}{c} n \\eta n \end{array} \right) \left( \sum_x k_G^{\alpha, \beta, x}(\eta) \right)^{\Delta-1} \left( \sum_x k_G^{\alpha, \beta, x} \right), \quad (104)
\]

87
where the sum over $\alpha, \beta$ ranges in $\Sigma^P$ and the sums over $x$’s range in $M_1(\alpha + n^+ / n, \beta + n^- / n)$ and $M_1(\alpha, \beta)$ respectively.

To compute $E_{G_n}[Z^P_G(\eta) X_\ell]$, we again decompose $X_\ell$ as before, so that

$$E_{G_n}[Z^P_G(\eta) X_\ell] = \frac{1}{2^\ell} \sum_{\xi} \sum_{\zeta} p_{1} E_{G_n}[Z^P_G(\eta) | 1_{\xi, \zeta}].$$

It will suffice thus to compute $E_{G_n}[Z^P_G(\eta) | 1_{\xi, \zeta}] / E_{G_n}[Z^P_G(\eta)]$. Keeping the same definitions for $a(k), a_{i[q]}, a_{i[q]}, a_{i+}(k), a_{i-}(k), a(k)$, for $k = 1, \ldots, \Delta - 1$, let

$$\kappa_{G, \alpha, \beta, x, k}(\eta) = \left( n + r - a(k) \right)^{-1} \prod_i \left( \alpha_i n - a_{i[q]}(k) \right) \prod_j \left( \beta_j n - a_{i[q]}(k) \right),$$

while for $k = \Delta$, let

$$\kappa_{G, \alpha, \beta, x, \Delta} = \left( n - a(k) \right)^{-1} \prod_i \left( \alpha_i n - a_{i[q]}(k) \right) \prod_j \left( \beta_j n - a_{i[q]}(k) \right),$$

We have that

$$E_{G_n}[Z^P_G(\eta)] = \sum_{\alpha, \beta} \left( n \right) \left[ \frac{\prod_{k=1}^{\Delta-1} \left( \sum_{\kappa_{G, \alpha, \beta, x, k}(\eta) \right)} \left( \sum_{\kappa_{G, \alpha, \beta, x, \Delta} \right) \right]. \quad (105)$$

The previous calculations show that

$$\kappa_{G, \alpha, \beta, x, \Delta} \sim \frac{\prod_{i,j} (x_{ij})^{a_{ij}(\Delta)}}{\prod_{\alpha_i} \sum_{a_{ij}(\Delta)} \prod_{\beta_j} \sum_{a_{ij}(\Delta)}}$$

Moreover, we have

$$\frac{\left( \alpha_i n + n^+ - a_{i+}(k) \right)}{\left( \alpha_i n - a_{i[q]}(k) \right)} \sim \frac{\prod_i x_{ij}^{a_{i+}(k)}}{\prod_i x_{ij}^{a_{i[q]}(k)}}$$

yielding

$$\frac{E_{G_n}[Z^P_G(\eta) | 1_{\xi, \zeta}]}{E_{G_n}[Z^P_G(\eta)]} \sim \frac{\prod_{i,j} (x_{ij})^{a_{ij}}}{\prod_{\alpha_i} \sum_{a_{ij}} \prod_{\beta_j} \sum_{a_{ij}}}.$$ 

exactly as before. Hence, the rest of the proof for the variables $Z^P_G(\eta)$ is exactly the same as for the variables $Z^\alpha, \beta(\eta)$.

Proof of Lemma 39. Using Lemma 36, we have

$$\sum_{i \geq 2} \mu_i \delta_i^2 = \sum_{i \geq 2} \left( \frac{r(\Delta, i)}{i} \right) \left( \sum_{j=1}^{q-1} \lambda_j^i \right)^2 = \sum_{i \geq 2} \left( \frac{(\Delta - 1)^i + (\Delta - 1)}{i} \right) \left( \sum_{j=1}^{q-1} \sum_{j'=1}^{q-1} \lambda_j^i \lambda_{j'}^i \right).$$

88
Observe that $\sum_{j \geq 1} \frac{x^2_j}{\lambda_j} = -\frac{1}{2} \ln(1 - x^2)$ for all $|x| < 1$. By Item 1 of Lemma 35, the $\lambda_j$’s satisfy $(\Delta - 1)\lambda_j < 1$ for all $j$, so that $(\Delta - 1)\lambda_j \lambda_j' < 1$ for all $j, j'$. It follows that

$$\sum_{\text{even } i \geq 2} \mu_i \delta_i^2 = -\frac{1}{2} \left( \sum_{i,j} \ln \left( 1 - (\Delta - 1)^2 \lambda_i^2 \lambda_j^2 \right) + (\Delta - 1) \sum_{i,j} \ln \left( 1 - \lambda_i^2 \lambda_j^2 \right) \right),$$

thus proving the first part of the lemma. The proof of $\sum_i \mu_i \delta_i < \infty$ is completely analogous.

4.3 Moment Asymptotics

In this section we compute the asymptotics of the moments. For a dominant phase $p = (\alpha, \beta)$ (cf. Definition 5, we will be interested in the asymptotics of $E_G[Z_\alpha^p, \beta G]$, $E_G[(Z_\alpha^p)^2]$, $E_G[Z_\alpha^p G]$, $E_G[(Z_\alpha^p)^2]$. It would be sufficient for the arguments in the previous sections to find the asymptotics of $Z_\alpha^p G$, but the computation of the moments of $Z_\alpha^p G$ is also interesting.

To justify this point, our techniques to compute the moment asymptotics extend to local maxima $(\alpha, \beta)$ of $\Psi_1(\alpha, \beta)$, provided that one has analogues of Theorem 4 and Lemma 28 (to control the maximizer of $\Psi_2(\alpha, \beta)$).

The main idea behind the calculation of the moment asymptotics is that the sums in (22) and (24) are determined by the terms with the largest contribution. For example, to compute the asymptotics of $E_G[Z_\alpha^p, \beta G]$, we need to consider the vector $x^*$ which maximizes $\Upsilon_1(\alpha, \beta, x)$ and integrate over the vectors $x$ which are close to $x^*$. Provided that the Hessian of $\Upsilon_1(\alpha, \beta, x)$ at $x^*$ is negative definite, we obtain a Gaussian integral which can be computed in terms of the determinant of the Hessian. A similar approach applies to compute the asymptotics of $E_G[(Z_\alpha^p)^2]$; there, we need to consider $(\gamma^*, \delta^*, y^*)$ which maximize $\Upsilon_2(\gamma, \delta, y)$ and integrate over $(\gamma, \delta, y)$ which are close to $(\gamma^*, \delta^*, y^*)$. Note that the $x^*$ and $(\gamma^*, \delta^*, y^*)$ are unique; see Remark 5 for details. To lighten notation, we will drop the stars from the maximizers when clear from context.

To perform the integrations accurately, we will need to ensure that the integration variables lie in a full dimensional space. This requires a slightly different view of the domain of the functions $\Upsilon_1$ and $\Upsilon_2$, which we refer to as the full dimensional representation. We will
also have to take care of a minor technical detail relative to the presence of hard constraints. Such considerations were circumvented in the maximization of $\Upsilon_1$ and $\Upsilon_2$, but here it will be cleaner to explicitly deal with them in a slightly more combinatorial fashion. We do this in the context of the calculations needed for the asymptotics of $E_G[(Z_G^{\alpha,\beta})]$ and $E_G[(Z_G^{\alpha,\beta})^2]$, respectively.

### 4.3.1 Full Dimensional Representations

For the first moment, $E_G[(Z_G^{\alpha,\beta})]$ is a sum over $x$ while $\alpha, \beta$ are fixed. Let

$$P_1 = \{(i, j) \in [q]^2 \mid B_{ij} > 0\}.$$  \hfill (106)

In the presence of a hard constraint $B_{ij} = 0$, edge assignments $(i, j)$ have zero weight and hence correspond to a non-permissible configuration. In the maximization of $\Upsilon_1$, the hard constraint $B_{ij} = 0$ was not directly relevant, since for $x_{ij} > 0$ the function $\Upsilon_1$ evaluates to $-\infty$. Indeed, we found that the optimal $x_{ij}$ is of the form $B_{ij}R_iC_j$ and hence zero. However, the asymptotics in which we are interested include products of the optimal values of the $x_{ij}$ and to correctly capture them, we need to explicitly rule out the zero values.

To do so, in the formulation (21), we hard-code $x_{ij} = 0$ for a pair $(i, j) \notin P_1$ and hence the variables $x$ are restricted to the space

$$\sum_j x_{ij} = a_i \quad (\forall i \in [q]), \quad \sum_i x_{ij} = b_j \quad (\forall j \in [q]),$$

$$x_{ij} = 0 \quad (\forall (i, j) \in [q]^2 \setminus P_1), \quad x_{ij} \geq 0 \quad (\forall (i, j) \in P_1).$$  \hfill (107)

Note that the dimension of the polytope (107) is $|P_1| - (2q - 1)$ since the matrix $B$ is irreducible. To get affinely independent variables $x$, we use the equalities in (107) and substitute an appropriate set of $(q - 1)^2 - |P_1|$ variables. We will not need to understand these substitutions till Section 4.4.1, yet in the integrations which follow it is preferable to have integration variables rather than integrate over subspaces.

After this process, we are going to have $|P_1| - (2q - 1)$ variables lying in a full dimensional space. We refer to this set of variables as the full dimensional $x$. We still use the notation $x$ for these variables and refer to $x_{ij}$ even if $x_{ij}$ is not in the representation $x$, under the understanding that this is just a shorthand for the substituted expression. Using these
Lemma 41. Suppose that $\Psi_1(\alpha, \beta, x)$ is now a function of the full dimensional $x$, and we will refer to this setup as the full dimensional representation of $\Psi_1$.

For the second moment, $E_G[(Z_G^{\alpha, \beta})^2]$ is a sum over $\gamma, \delta, y$ while $\alpha, \beta$ are fixed. Let $$P_2 = \{(i, k, j, l) \in [q]^4 \mid B_{ikjl} > 0\}.$$ Since $B_{ikjl} = B_{ij}B_{kl}$, we clearly have $|P_2| = |P_1|^2$. As above, we now restrict $\gamma, \delta, y$ to lie in the space
\[
\sum_k \gamma_{ik} = \alpha_i \quad (\forall i \in [q]), \quad \sum_l \delta_{jl} = \beta_j \quad (\forall j \in [q]), \quad \sum_{jl} y_{ikjl} = \gamma_{ik} \quad (\forall (i, k) \in [q]^2) \\
\sum_i \gamma_{ik} = \alpha_k \quad (\forall k \in [q]), \quad \sum_j \delta_{jl} = \beta_l \quad (\forall l \in [q]), \quad \sum_{ik} y_{ikjl} = \delta_{jl} \quad (\forall (j, l) \in [q]^2) \\
\gamma_{ik} \geq 0 \quad (\forall (i, k) \in [q]^2), \quad \delta_{jl} \geq 0 \quad (\forall (j, l) \in [q]^2), \quad y_{ikjl} \geq 0 \quad (\forall (i, k, j, l) \in P_2), \\
y_{ikjl} = 0 \quad (\forall (i, k, j, l) \in [q]^4 \setminus P_2).
\]

Once again, note the extra equality constraints relative to the original formulation (23). The same remarks and conventions apply as in the case of the first moment. Therefore, we obtain full dimensional $(\gamma, \delta, y)$ and a full dimensional representation of $\Psi_2(\gamma, \delta, y)$. We point out that in the full dimensional $(\gamma, \delta, y)$, there are $(q - 1)^2$ variables $\gamma_{ik}$, $(q - 1)^2$ variables $\delta_{jl}$ and $|P_2| - (2q^2 - 1)$ variables $y_{ikjl}$.

The following two lemmas express the asymptotics of the moments in terms of suitable determinants. Thus, to compute the asymptotics of the ratio $E_G[(Z_G^{\alpha, \beta})^2]/(E_G[Z_G^{\alpha, \beta}])^2$, it suffices to compute the determinants appearing in the above two lemmas. This is a long and twisted road and is deferred to Section 4.4.2, where also the proof of Lemma 40 is completed.

**Lemma 41.** Suppose that $(\alpha, \beta)$ maximize $\Psi_1$. Let $x$ be the (unique) maximizer of $\Psi_1$. Denote by $H_1$ be the Hessian of the full dimensional representation of $\Psi_1(\alpha, \beta, x)$ scaled by $1/\Delta$ and by $H_{1,x}$ the square submatrix of $H_1$ corresponding to rows and columns indexed by $x$. Then
\[
\lim_{n \to \infty} \frac{(2\pi n)^{q-1} E_G[Z_G^{\alpha, \beta}]}{e^{n \Psi_1(\alpha, \beta, x)}} = \frac{\left(\prod_i \alpha_i \prod_j \beta_j\right)^{(\Delta - 1)/2} \left(\prod_{(i,j) \in P_1} x_{ij}\right)^{-\Delta/2}}{(\text{Det}(-H_{1,x}))^{\Delta/2}}.
\]

91
Lemma 42. Suppose that \((\alpha, \beta)\) maximize \(\Psi_1\). Let \((\gamma, \beta, y)\) be the (unique) maximizer of \(\Upsilon_2\). Denote by \(H_2\) be the Hessian of the full dimensional representation of \(\Upsilon_2(\gamma, \delta, y)\) scaled by \(1/\Delta\) and \(H_{2,y}\) the square submatrix of \(H_2\) corresponding to rows and columns indexed by \(y\). Then

\[
\lim_{n \to \infty} \frac{(2\pi n)^{2(q-1)}}{e^{n\Upsilon_2(\gamma, \delta, y)}} E_G[(Z_G^{\alpha, \beta})^2] = \left(\prod_{i,k} \gamma_{ik} \prod_{j,l} \delta_{jl}\right)^{(\Delta - 1)/2} \left(\prod_{(i,k,j,l) \in P_2} y_{ikjl}\right)^{-\Delta/2} \Delta^{(q-1)/2} \left(\text{Det}(H_2)\right)^{1/2} \left(\text{Det}(-H_{2,y})\right)^{(\Delta - 1)/2}.
\]

The proofs of Lemmas 41 and 42 are similar; we give the proof of Lemma 42 which is a bit tricky due to a two step integration.

Proof of Lemma 42. We assume a full dimensional representation of \((\gamma, \delta, y)\). We denote by \((\gamma^*, \delta^*, y^*)\) the optimal vector which maximizes the full dimensional representation of \(\Upsilon_2(\gamma, \delta, y)\). We have that \(\gamma_{ik}^*, \delta_{jl}^* > 0\) for all \(i, k, j, l\) and \(y_{ikjl}^* > 0\) for \((i, k, j, l) \in P_2\). Pick \(\delta\) sufficiently small such that:

\[
\lVert(\gamma, \delta, y) - (\gamma^*, \delta^*, y^*)\rVert_2 \leq \delta \text{ implies } \gamma_{ik}, \delta_{jl} > 0 \text{ for all } i, k, j, l \text{ and } y_{ikjl} > 0 \text{ for } (i, k, j, l) \in P_2.
\]

Since \(\Upsilon_2\) has a unique global maximum \((\gamma^*, \delta^*, y^*)\) in the space (109), standard compactness arguments imply that there exists \(\varepsilon(\delta) > 0\) such that \(\|(\gamma, \delta, y) - (\gamma^*, \delta^*, y^*)\| \geq \delta\) implies \(\Upsilon_2(\gamma^*, \delta^*, y^*) - \Upsilon_2(\gamma, \delta, y) \geq \varepsilon\). It follows that the contribution of terms with \(\|(\gamma, \delta, y) - (\gamma^*, \delta^*, y^*)\| \geq \delta\) to \(E_G[(Z_G^{\alpha, \beta})^2]\) may be safely ignored. Hence we may restrict our attention to \(\gamma, \delta, y\) satisfying \(\|(\gamma, \delta, y) - (\gamma^*, \delta^*, y^*)\| < \delta\). Moreover, using Taylor’s expansion, we may choose \(\delta\) small enough such that \(\Upsilon_2\) decays quadratically in a \(\delta\)-ball around \((\gamma^*, \delta^*, y^*)\).

Utilizing the choice of \(\delta\) and Stirling’s approximation for factorials, we thus obtain

\[
E_G[(Z_G^{\alpha, \beta})^2] = \left(1 + O(n^{-1})\right) \frac{1}{(2\pi n)^{2(q-1)}} \sum_{\gamma, \delta} \left(\prod_{i,k} \gamma_{ik} \prod_{j,l} \delta_{jl}\right)^{(\Delta - 1)/2} \left(\prod_{(i,k,j,l) \in P_2} y_{ikjl}\right)^{-\Delta} \left[\sum_{y} \frac{1}{\sqrt{2\pi n}} |P_2|^{-2q/2} \left(\prod_{(i,k,j,l) \in P_2} \frac{1}{y_{ikjl}^{1/2}}\right) e^{n(\Upsilon_2(\gamma, \delta, y) - \Upsilon_2(\gamma, \delta, y^*))}/\Delta\right].
\]

We now compute

\[
L = \lim_{n \to \infty} \frac{(2\pi n)^{2(q-1)}}{e^{n\Upsilon_2(\gamma^*, \delta^*, y^*)}} E_G[(Z_G^{\alpha, \beta})^2].
\]
Standard techniques of rewriting sums as integrals and an application of the dominated
convergence theorem (see for example [26, Section 9.4]) ultimately give
\[ L = \left(\frac{1}{2}\right)^{(q-1)/2}\left(\prod_{i,k} \gamma_i^* \prod_{j,l} \delta_{jl}^*\right)^{\Delta - 1/2} \left(\prod_{(i,k,j,l) \in P_2} y_{ikjl}^*\right)^{-\Delta/2} \]
\[ \left(\frac{1}{\sqrt{2\pi}}\right)^{2(q-1)^2} \int_{-\infty}^{\infty} \cdots \int_{-\infty}^{\infty} \left[ \left(\frac{1}{\sqrt{2\pi}}\right)^{|P_2|-(2q^2-1)} \int_{-\infty}^{\infty} \cdots \int_{-\infty}^{\infty} e^{\frac{1}{2}(\gamma,\delta, y)^T H^{\gamma}}(\gamma,\delta, y)^T dy\right]^{\Delta} d\gamma d\delta, \]
where \( H \) denotes the Hessian matrix of \( \Upsilon_2 \) evaluated at \((\gamma^*, \delta^*, y^*)\) scaled by \(1/\Delta\) and the
operator \( \cdot \) stands for matrix multiplication.

We thus focus on computing the integral in (110). We begin with the inner integration. Let
\[ I_1 = \left[ \left(\frac{1}{\sqrt{2\pi}}\right)^{|P_2|-(2q^2-1)} \int_{-\infty}^{\infty} \cdots \int_{-\infty}^{\infty} e^{\frac{1}{2}(\gamma,\delta, y)^T H^{\gamma}}(\gamma,\delta, y)^T dy\right]^{\Delta}. \]
To calculate \( I_1 \), we first decompose the exponent to isolate the terms involving \( y \). We obtain
\[ \frac{1}{2}(\gamma, \delta, y)^T H (\gamma, \delta, y)^T = \frac{1}{2}(\gamma, \delta)^T H_{\gamma,\delta} (\gamma, \delta)^T - \frac{1}{2} y^T (-H_y) y + T \cdot y^T, \]
where \( H = \begin{pmatrix} H_{\gamma,\delta} & H_{\gamma\delta, y} \\ H_{\gamma\delta, y}^T & H_y \end{pmatrix} \) and \( T = (\gamma, \delta)^T H_{\gamma,\delta, y} \). Specifically:
- \( H_{\gamma,\delta} \) is the square submatrix of \( H \) corresponding to the rows indexed by \( \gamma, \delta \) and the columns indexed by \( \gamma, \delta \),
- \( H_y \) is the square submatrix of \( H \) corresponding to the rows indexed by \( y \) and the columns indexed by \( y \),
- \( T = (\gamma, \delta)^T H_{\gamma\delta, y} \), where \( H_{\gamma\delta, y} \) is the submatrix of \( H \) corresponding to the rows indexed by \( \gamma, \delta \) and the columns indexed by \( y \).

Note that \( H_y \) is the Hessian of \( g_2(y) \) evaluated at \( y^* \). Since \( g_2(y) \) is concave, we have that
\( H_y \) is negative definite. Utilizing this decomposition, we obtain
\[ I_1 = e^{\frac{\Delta}{2}(\gamma, \delta)^T H_{\gamma,\delta} (\gamma, \delta)^T} \left[ \left(\frac{1}{\sqrt{2\pi}}\right)^{|P_2|-(2q^2-1)} \int_{-\infty}^{\infty} \cdots \int_{-\infty}^{\infty} e^{-\frac{1}{2} y^T (-H_y) y + T \cdot y^T} dy\right]^{\Delta} \]
\[ = \frac{1}{(\text{Det}(-H_y))^{\Delta/2}} e^{\frac{\Delta}{2} (T \cdot (-H_y)^{-1} T^T + (\gamma, \delta)^T H_{\gamma,\delta} (\gamma, \delta)^T)}. \]
We are left with the task of computing the integral
\[ I_2 = \left( \frac{1}{\sqrt{2\pi}} \right)^{2(q-1)^2} \int_{-\infty}^{\infty} \cdots \int_{-\infty}^{\infty} e^{\frac{1}{2} (T(-H_y)^{-1}:T^T + (\gamma, \delta) \cdot H_{\gamma, \delta} \cdot (\gamma, \delta)^T) / 2} \, d\gamma \, d\delta. \] (111)

Using the definition of \( T \), we have
\[ T \cdot (-H_y)^{-1} \cdot T^T + (\gamma, \delta) \cdot H_{\gamma, \delta} \cdot (\gamma, \delta)^T = (\gamma, \delta) \cdot (H_{\gamma, \delta} - H_{\gamma \delta, y} \cdot H_y^{-1} \cdot H_{\gamma \delta, y}^T) \cdot (\gamma, \delta)^T. \]

The matrix \( M = H_{\gamma, \delta} - H_{\gamma \delta, y} \cdot H_y^{-1} \cdot H_{\gamma \delta, y}^T \) is the Schur complement of the block \( H_y \) of \( H \).

In fact, we have the identity \( \text{Det}(H) = \text{Det}(H_y) \cdot \text{Det}(M) \) and in particular \( M \) is negative definite. A Gaussian integration then yields
\[ I_2 = \left( \frac{1}{\Delta^{2(q-1)^2} \text{Det}(-M)} \right)^{1/2} = \left( \frac{\text{Det}(-H_y)}{\Delta^{2(q-1)^2} \text{Det}(-H)} \right)^{1/2}. \] (112)

Combining equations (110), (111), (112), we obtain the statement of the Lemma. \( \square \)

4.4 The Determinants

This section addresses the computation of the determinants of the Hessians in Lemmas 41 and 42. The calculations are quite complex since one has to make a choice of free variables, do the substitutions, differentiate, and then hope that the structure of the problem will prevail in the determinants. Pushing this procedure in our setting leads to complications since the choice of free variables takes away much of the combinatorial structure of the problem.

We follow a different path, which amongst other things, reveals that the determinants, via the matrix-tree theorem, correspond to counting weighted trees in appropriate graphs.

The proof has two parts. The first part connects different formulations of the Hessian of a constrained maximization in an abstract setting. Essentially, this puts together well known concepts from optimization in a way that will allow to stay as close as possible to the combinatorial structure of the determinants. The second part specialises the work of the first part to compute the required determinants and is unavoidably more computational.

4.4.1 Hessian formulations for Constrained problems

The setting of this section is the following: we are given \( \Upsilon \), a function of \( z \in \mathbb{R}^n \), subject to the linear constraints \( Az = b \), where \( A \in \mathbb{R}^{m \times n} \). The assumption of linear constraints
stems from the setting of Lemmas 41 and 42, yet the arguments extend to other constraints as well by considering gradients of these constraints at the point \( z_0 \) and implicit functions. Wlog, we will also assume that \( b = 0 \).

We are interested in the Hessian \( H^f \) of a full dimensional representation of \( \Upsilon \). A full dimensional representation of \( \Upsilon \) consists essentially of substituting an appropriate subset of the variables \( z \) using the constraints \( Az = 0 \). Note that the representation is not as much tied to \( \Upsilon \) as it is tied to the space \( Az = 0 \). Specifically, assume that the row rank of \( A \) is \( r \). In all the relevant constrained functions we consider, the constraints are not linearly independent so such an assumption is necessary. A full dimensional representation of \( \Upsilon \) is specified by two submatrices of \( A \) denoted by \((A_f, A_{fs})\). The matrix \( A_f \) is a submatrix of \( A \) consisting of \( r \) linearly independent rows of \( A \), so that \( Az = 0 \) iff \( A_f z = 0 \). Then, \( A_{fs} \) is an \( r \times r \) submatrix of \( A_f \) which is invertible. The variables corresponding to columns of \( A_{fs} \) are denoted by \( z_s \). The remaining variables \( z_f \) are called free and \( A_{ff} \) is the submatrix of \( A_f \) induced by the columns indexed by \( z_f \). Renaming if needed, the equation \( A_f z = 0 \) may be naturally decomposed as

\[
\begin{bmatrix}
A_{ff} & A_{fs} \\
\end{bmatrix}
\begin{bmatrix}
z_f \\
z_s \\
\end{bmatrix}
= 0,
\]

so that

\[
z = \begin{bmatrix}
z_f \\
z_s \\
\end{bmatrix} = \begin{bmatrix}
I \\
-(A_{fs})^{-1}A_{ff} \\
\end{bmatrix}z_f.
\]

Thus, we can now think of \( \Upsilon \) as a function which is completely determined by the variables \( z_f \) which, in contrast with the variables \( z \), span a full dimensional space.

Denote by \( H \) the unconstrained Hessian of \( \Upsilon \) with respect to the variables \( z \) and by \( H^f \) the Hessian of the full dimensional representation of \( \Upsilon \) with respect to the variables \( z_f \). The Hessians \( H, H^f \) are connected by the following equation, which follows by straightforward matrix calculus and its proof is omitted.

\[
H^f = S^T H S, \quad \text{where } S = \begin{bmatrix}
I \\
-(A_{fs})^{-1}A_{ff} \\
\end{bmatrix}.
\]  

(113)

Note that \( H^f \) is different, though closely related, from the constrained Hessian \( H^c \) of \( \Upsilon \) in the subspace \( Az = 0 \), see for example [35, Chapter 10]. The constrained Hessian \( H^c \) has infinitely many matrix representations, all of which correspond to similar matrices, that is,
matrices with the same set of eigenvalues. A matrix representation may be obtained by first picking an orthonormal basis of the \((n - r)\)-dimensional space \(\{z \mid Az = 0\}\). Let \(E\) denote the \(n \times (n - r)\) matrix whose columns are the vectors in the basis. Then a matrix representation of \(H^c\) is given by

\[
H^c = E^\top HE,
\]

where \(H\) is as before the unconstrained Hessian of \(\Upsilon\) with respect to the variables \(z\). We are ready to prove the following. It is useful to recall here that congruent matrices have the same number of negative, zero and positive eigenvalues.

**Lemma 43.** \(H^f\) is congruent to any matrix representation of \(H^c\). Moreover, it holds that

\[
\det(H^f) = \det(H^c)\det(A_fA_f^\top)/(\det(A_{fs})^2).
\]

**Proof of Lemma 43.** The columns of the matrix \(S\) defined in equation (113) form a basis of the space \(\{z \mid Az = 0\}\). Indeed, \(S\) has clearly full column rank and also \(A_fS = 0\) implying \(AS = 0\) as well. For future use, by a direct evaluation

\[
S^\top S = I + A_f^\top (A_{fs}A_{fs}^\top)^{-1}A_{ff},
\]

so \(\det(S^\top S) = \det(I + A_{ff}A_f^\top (A_{fs}A_{fs}^\top)^{-1})\),

where the latter equality uses Sylvester’s determinant theorem. This clearly yields

\[
\det(S^\top S) = \det(A_fA_f^\top)/(\det(A_{fs})^2).
\]

Comparing (113) and (114), the only difference is that \(S\) does not necessarily encode an orthonormal basis. Nevertheless, there clearly exists an invertible matrix \(P\) such that \(SP\) consists of orthonormal columns, for example by the Gram-Schmidt process on the columns of \(S\). It follows that \(P^\top H^f P\) is a matrix representation of \(H^c\). This proves the first part of the lemma and also gives \(\det(H^c) = \det(H^f)\det(P)^2\).

For the second part, the selection of \(P\) implies that \((SP)^\top SP\) is the identity matrix and hence \(\det(S^\top S)\det(P)^2 = 1\). The desired equality follows.

**Lemma 43** allows us to focus on the determinant of \(H^c\) or equivalently the product of its eigenvalues. The latter may be handled using bordered Hessians. Specifically, let \(A_f\) be
any submatrix of \( A \) induced by \( r \) linearly independent rows. Then, \( \lambda \) is an eigenvalue of \( H^c \) iff it is a root of the polynomial

\[
p(\lambda) = \text{Det}
\begin{bmatrix}
0 & A_f \\
-A_f^\top & H - \lambda I_n
\end{bmatrix}
\]  
(116)

In our case, deleting rows of \( A \) to obtain \( A_f \) would cause undesirable complications. In the following, we circumvent such deletions by adding suitable “perturbations”. We will also allow for certain degrees of freedom to select the perturbations which will be exploited in the computations. We first prove the following.

For a polynomial \( p(s) \), \([s^t]p(s)\) denotes the coefficient of \( s^t \) in \( p(s) \).

**Lemma 44.** Let \( M \in \mathbb{R}^{m \times m} \) be a symmetric matrix with rank \( r \) and let \( \mu_i, i = 1, \ldots, m \) be the eigenvalues of \( M \) with corresponding unit eigenvectors \( v_i \), where \( \{v_1, \ldots, v_m\} \) is an orthonormal basis of \( \mathbb{R}^m \). Then, for any symmetric matrix \( T \in \mathbb{R}^{m \times m} \), it holds that

\[
[\varepsilon^{m-r}] \text{Det}(\varepsilon T + M) = \prod_{i: \mu_i \neq 0} \mu_i \prod_{i: \mu_i = 0} v_i^\top T v_i,
\]  
(117)

In particular, if \( T \) is positive semidefinite and \([T M]\) has full row rank, the rhs of (117) is non-zero.

**Proof of Lemma 44.** Let \( M(\varepsilon) = \varepsilon T + M \) and denote by \( \mu_i(\varepsilon), v_i(\varepsilon) \) the eigenvalues and unit eigenvectors of \( M(\varepsilon) \). Rellich’s theorem asserts that \( \mu_i(\varepsilon) \) and \( v_i(\varepsilon) \) are analytic functions of \( \varepsilon \) around \( \varepsilon = 0 \). By Hadamard’s first variation formula, we have \( \frac{\partial \mu_i}{\partial \varepsilon} = v_i^\top \frac{\partial M}{\partial \varepsilon} v_i \). At \( \varepsilon = 0 \), \( M \) has rank \( r \) and hence exactly \( m - r \) eigenvalues are zero. Thus, for small enough \( \varepsilon \),

\[
\text{Det}(M(\varepsilon)) = \varepsilon^{m-r} \prod_{i: \mu_i \neq 0} \mu_i \prod_{i: \mu_i = 0} v_i^\top T v_i + O(\varepsilon^{m-r+1}).
\]

Hence, \([\varepsilon^{m-r}]\text{Det}(M(\varepsilon)) \neq 0 \) if for every \( v_i \neq 0 \) such that \( Mv_i = 0 \), we have \( v_i^\top T v_i \neq 0 \). The latter is true. Otherwise, using the positive semidefiniteness of \( T \), we obtain \( v_i^\top [T M] = 0 \), contradicting that \([T M]\) has full row rank.

The following lemma gives the promised extension of (116).
Lemma 45. Suppose that $T$ is a diagonal positive semidefinite $m \times m$ matrix such that $[T \ A]$ has full row rank. Let $H$ (resp. $H^c$) be the unconstrained (resp. constrained) Hessian of $\Upsilon$ evaluated at a point $z_0$. Then, $\lambda$ is an eigenvalue of $H^c$ iff it is a root of the polynomial

$$p(\lambda) = [\varepsilon^{m-r}] \text{Det}(H_{\lambda}) \text{ where } H_{\lambda} = \begin{bmatrix} \varepsilon T & A \\ -A^\top & H - \lambda I_n \end{bmatrix}. \quad (118)$$

Further, if $H$ is invertible, then

$$\text{Det}(H^c) = (-1)^n \text{Det}(H) \frac{[\varepsilon^{m-r}] \text{Det}(\varepsilon T + AH^{-1}A^\top)}{[\varepsilon^{m-r}] \text{Det}(\varepsilon T - AA^\top)}.$$ 

Proof of Lemma 45. Let $T = (t_{i,j})_{i,j \in [m]}$ and $H_{\lambda} = (h_{i,j})_{i,j \in [m+n]}$. Let $W = \binom{[m]}{m-r}$ and for $W \in W$ let $P_W = \{ \sigma \in S_{m+n} \mid \{i \in [m] \mid \sigma(i) = i\} = W\}$. Since $T$ is diagonal, by Leibniz’s formula,

$$p(\lambda) = [\varepsilon^{m-r}] \text{Det}(H_{\lambda}) = \sum_{W \in W} \prod_{i \in W} t_{i,i} \sum_{\sigma \in P_W} \text{sgn}(\sigma) \prod_{i \in [m+n]\setminus W} h_{i,\sigma(i)}. \quad (119)$$

Let $A_{[m]\setminus W}$ be the $r \times n$ submatrix of $A$ which is obtain by excluding the rows indexed by $W$. Identifying permutations in $P_W$ with permutations of $[n+r]$ in the natural way, we obtain

$$\sum_{\sigma \in P_W} \text{sgn}(\sigma) \prod_{i \in [m+n]\setminus W} h_{i,\sigma(i)} = \text{Det}\left(\begin{bmatrix} 0_r & A_{[m]\setminus W} \\ -A_{[m]\setminus W}^\top & H - \lambda I_n \end{bmatrix}\right) \equiv q_W(\lambda). \quad (120)$$

If $A_{[m]\setminus W}$ has row rank $< r$, then $q_W(\lambda)$ is 0. Otherwise, the roots of $q_W(\lambda)$ are the eigenvalues of $H^c$, c.f. (116). By (119), this is also the case for $p(\lambda)$, provided it is not identically zero.

To prove that $p(\lambda)$ is nonzero, we prove that the leading coefficient of $p(\lambda)$ is nonzero. Starting from (120) and plugging into (119), this can easily be seen to equal

$$[\varepsilon^{m-r}] \text{Det}\left(\begin{bmatrix} \varepsilon T & A \\ -A^\top & -I_n \end{bmatrix}\right) = [\varepsilon^{m-r}] (-1)^n \text{Det}(\varepsilon T - AA^\top),$$

where in the latter equality we used the Schur complement of the block $-I_n$. This is non-zero by Lemma 44.

The determinant of $H^c$ is the product of its eigenvalues. This equals $p(0)$ divided by the leading coefficient of $p(\lambda)$. The latter has already been computed. The former, using
the Schur complement of the invertible $H$, is equal to $[\varepsilon^{m-r}] \text{Det}(H) \text{Det}(\varepsilon T - AH^{-1}A^\top)$.

This concludes the proof. \hfill \square

Finally, we combine the above lemmas to obtain the following.

**Lemma 46.** Let $\Upsilon$ be a function of $z \in \mathbb{R}^n$ subject to the linear constraints $Az = b$, where $A \in \mathbb{R}^{m \times n}$ where $A$ has rank $r$. Let $(A_f, A_{fs})$ specify a full dimensional representation of $\Upsilon$ and let $H^f$ be the corresponding Hessian of $\Upsilon$ evaluated at a point $z_0$.

Suppose $T$ is a positive semidefinite diagonal matrix with dimensions $m \times m$ such that $[T A]$ has full row rank. Let $H$ (resp. $H^c$) be the unconstrained Hessian of $\Upsilon$ evaluated at $z_0$. If $H$ is invertible, then

$$\text{Det}(-H_f) = \frac{L(A_f, A, T)}{\text{Det}(A_{fs})^2} \text{Det}(H) \varepsilon^{m-r} \text{Det}(\varepsilon T - AH^{-1}A^\top),$$

(121)

where $L(A_f, A, T) = \text{Det}(A_f A_f^\top)/[\varepsilon^{m-r}] \text{Det}(\varepsilon T - AA^\top)$.

**Proof of Lemma 46.** Just combine Lemmas 43 and 45. The minor sign change $-H^f$ in the statement can easily be accounted by applying the lemmas to the function $-\Upsilon$. \hfill \square

The rhs of (121) has two qualitatively different factors: the factor $L(A_f, A, T)/\text{Det}(A_{fs})^2$ depends on the specific full dimensional representation, while the remaining factor is tied to the Hessian of $\Upsilon$. The technical convenience of Lemma 46 is dual: first, it gives an explicit formula for $\text{Det}(-H^f)$ without doing substitutions which would hinder the combinatorial view of the constraints $A$; second, it isolates the deletions of rows of $A$ in the factor $L(A_f, A)$ and leaves untouched the more complicated matrix $AH^{-1}A^\top$.

**4.4.2 The Computations**

In this section, we utilize Lemma 46 to compute the determinants in Lemmas 41 and 42.

**Notation:** For a vector $z \in \mathbb{R}^n$ we denote by $z^D$ the $n \times n$ diagonal matrix $\text{diag}\{z_1, \ldots, z_n\}$. For vectors $z_i \in \mathbb{R}^{m_i}$, $i = 1, \ldots, t$ we denote by $[z_1, \ldots, z_t]^\top$ the $\mathbb{R}^{\sum_i m_i}$ vector which is the concatenation of the vectors $z_1, \ldots, z_t$. For matrices $A$ and $B$, $A \otimes B$ will denote the Kronecker product of $A, B$, while $A \oplus B$ is the direct sum of $A, B$, that is, the block diagonal matrix $\text{diag}\{A, B\}$. The expression $\oplus_2 A$ is a shorthand for $A \oplus A$. Further, $I_n$ denotes
the identity matrix of dimensions \( n \times n \). Finally, \( \mathbf{1}_n, \mathbf{0}_n \) denote the all-one and all-zero \( n \)-dimensional vector.

To start, the equality constraints in (107) and (109) may be written in the form

\[
A_1 \mathbf{x} = \mathbf{0}, \quad A_2 \begin{bmatrix} \gamma, \delta, y \end{bmatrix}^T = \begin{bmatrix} \alpha, \alpha, \beta, \beta, \mathbf{0}_{2q^2} \end{bmatrix}^T.
\]

The matrices \( A_1 \) and \( A_2 \) have dimensions \( 2q \times (q^2 - |P_1|) \) and \( (4q^2 + 2q^2) \times (2q^2 + q^4 - |P_2|) \), respectively, where \( P_1, P_2 \) are defined in (106), (108). Note that we exclude from consideration variables \( x_{ij} \) and \( y_{ijkl} \) which are hard-coded to zero. This is done to ensure that the unconstrained Hessians are invertible, so that Lemma 46 applies directly. It will be useful to decompose the matrix \( A_2 \) as

\[
A_2 = \begin{bmatrix} A_{2,\gamma\delta} & 0 \\ -I_{2q^2} & A_{2,y} \end{bmatrix},
\]

where \( A_{2,\gamma\delta}, A_{2,y} \) have dimensions \( 4q \times 2q^2 \) and \( 2q^2 \times (q^4 - |P_2|) \), respectively.

The easiest way to handle the matrices \( A_1, A_{2,\gamma\delta}, A_{2,y} \) is as incidence matrices of appropriate bipartite graphs. This view will simplify the arguments significantly. In particular, for an undirected graph \( G \), we denote by \( A_G \) the 0,1 incidence matrix of \( G \), by \( R_G \) the adjacency matrix of \( G \), by \( D_G \) the diagonal matrix whose diagonal entries are equal to the degrees of the vertices in \( G \) and by \( \Lambda_G \) the matrix \( D_G + R_G \). We will also be interested in the case where the graph \( G \) is weighted. We assume that the weights on the edges are positive and are given by the diagonal entries of a square diagonal matrix \( W_G \). We denote by \( R^w_G, D^w_G, \Lambda^w_G \) the weighted versions of the matrices \( R_G, D_G, \Lambda_G \). It is well known and easy to check that

\[
A_G A_G^\top = \Lambda_G, \quad \Lambda_G W_G A_G^\top = \Lambda_G^w.
\]

Before defining graphs to which (123) will be applied, it will be useful to state the unconstrained Hessians. From Lemmas 41 and 42, the unconstrained Hessians of interest are:

(i) \( H_{1,x} \), the Hessian of \( \Upsilon_1 / \Delta \) with respect to \( \mathbf{x} \) when \( \alpha, \beta \) are fixed, 
(ii) \( H_{2,y} \), the Hessian of \( \Upsilon_2 / \Delta \) with respect to \( \mathbf{y} \) when \( \alpha, \beta, \gamma, \delta \) are fixed, 
(iii) \( H_2 \), the Hessian of \( \Upsilon_2 / \Delta \) with respect to \( \gamma, \delta, \mathbf{y} \) when \( \alpha, \beta \) are fixed. These three matrices are all diagonal and it is
straightforward to see

\begin{align*}
\text{Det}(H_{1,x})^{-1} &= (-1)^{q^2-|P_1|} \prod_{i,j \in P_1} x_{ij}, \\
\text{Det}(H_{2,y})^{-1} &= (-1)^{q^2-|P_2|} \prod_{(i,k,j,l) \in P_2} y_{ijkl}, \\
\text{Det}(H_2)^{-1} &= \text{Det}(H_{2,y})^{-1} \left( \frac{\Delta-1}{\Delta} \right)^{2q^2} \prod_{i,k \in [q]} \gamma_{ik} \prod_{j,l \in [q]} \delta_{jl}, \\
(\mathbf{H}_{1,x})^{-1} &= -x^D, \quad (\mathbf{H}_{2,y})^{-1} = -y^D, \quad (\mathbf{H}_2)^{-1} = \frac{\Delta}{\Delta-1} \gamma^D \oplus \frac{\Delta}{\Delta-1} \delta^D \oplus (\mathbf{H}_{2,y})^{-1}.
\end{align*}

(124)

We next proceed to the definition of the bipartite graphs for each of the above matrices. For \( A_{1,x} \), the related graph \( G_x \) is a bipartite graph with vertex bipartition \([q],[q]\) and an edge \((i,j)\) is present iff \((i,j)\) \(\in P_1\), that is, \(B_{ij} > 0\). Since \( B \) is symmetric and irreducible, \( G_x \) is undirected and connected. For \( A_{2,y} \), the related graph \( G_y \) is a bipartite graph with vertex bipartition \([q^2],[q^2]\) and an edge \((i,k),(j,l)\) is present iff \((i,k,j,l)\) \(\in P_2\), that is, \(B_{ikjl} > 0\). For \( A_{2,\gamma\delta} \), the graph has two connected components indexed by \(\gamma,\delta\), respectively. Each is isomorphic to the complete bipartite graph \( K_{q,q} \) with vertex bipartition \([q],[q]\).

We denote by \( A_{2,q,q}^2 \) the incidence matrix of \( K_{q,q} \), so that \( A_{2,\gamma\delta} = \oplus_2 A_{2,q,q}^2 \).

The weights on the edges of the graphs \( G_x, G_y, G_{\gamma\delta} \) are given in principle by (124). Explicitly, an edge \((i,j)\) in \( G_x \) has weight \(x_{ij}\), an edge \((i,k),(j,l)\) in \( G_y \) has weight \(y_{ijkl}\) and an edge \((i,j)\) in \( G_{\gamma\delta} \) is \(\gamma_{ij}\) if it belongs to the connected component indexed by \(\gamma\) and \(\delta_{ij}\) if it belongs to the connected component indexed by \(\delta\). The factor \(\Delta/(\Delta-1)\) in \((\mathbf{H}_2)^{-1}\) will be accounted otherwise. In the language of (123),

\begin{align*}
\mathbf{W}_{G_x} &= x^D, \quad \mathbf{W}_{G_y} = y^D, \quad \mathbf{W}_{G_{\gamma\delta}} = \gamma^D \oplus \delta^D.
\end{align*}

(125)

The otherwise straightforward application of (123) on each of the graphs \( G_x, G_y, G_{\gamma\delta} \) is useful to do explicitly in order to decompose the resulting matrices. In particular, since these graphs are undirected and bipartite, we have

\begin{align*}
\Lambda^w(G_x) &= \begin{bmatrix} \alpha^D & S_x \\ S_x^\top & \beta^D \end{bmatrix}, \quad \Lambda^w(G_y) = \begin{bmatrix} \gamma^D & S_y \\ S_y^\top & \delta^D \end{bmatrix}, \\
\Lambda^w(G_{\gamma\delta}) &= \begin{bmatrix} \alpha^D & S_\gamma \\ S_\gamma & \alpha^D \end{bmatrix} \oplus \begin{bmatrix} \beta^D & S_\delta \\ S_\delta & \beta^D \end{bmatrix}.
\end{align*}

(126) (127)
where $S_x, S_\gamma, S_\delta$ are the $q \times q$ matrices whose $(i,j)$ entries are $x_{ij}, \gamma_{ij}, \delta_{ij}$, respectively, and $S_y$ is the $q^2 \times q^2$ matrix whose $((i,k),(j,l))$ entry is $y_{ijkl}$. Note that the matrices $D^w$ were substituted using (107) and (109).

We are now ready to evaluate these matrices at a global maximum $(\alpha^*, \beta^*, x^*)$ of $\Upsilon_1$ and $(\gamma^*, \delta^*, y^*)$ of $\Upsilon_2$. From now on, we will not explicitly use asterisks in the notation with the understanding that the values of all the variables are fixed to their optimal values. Note by Lemma 28, we have

$$\gamma = \alpha \otimes \alpha, \quad \delta = \beta \otimes \beta, \quad y = x \otimes x. \quad (128)$$

We will apply Lemma 46 to the matrices $H_{1,x}, H_{2,y}, H_2$ using the matrices

$$T_1 = \alpha^D \oplus \beta^D, \quad T_{2,y} = \gamma^D \oplus \delta^D, \quad T_2 = \alpha^D \oplus \alpha^D \oplus \beta^D \oplus \beta^D \oplus 0_{2q^2}, \quad (129)$$

respectively. We first compute the determinants of $M_1 = \varepsilon T_1 - A_1 (H_{1,x})^{-1} A_1^T$, $M_{2,y} = \varepsilon T_{2,y} - A_{2,y} (H_{2,y})^{-1} A_{2,y}^T$, $M_2 = \varepsilon T_2 - A_2 (H_2)^{-1} A_2^T$, which contribute the most interesting factors in Lemma 46.

We begin with the simplest of these matrices, $M_1$. Note that $A_1$ has rank $2q - 1$, so by Lemma 46 we want to compute $[\varepsilon] \det(M_1)$. Using (123), (124), (125), (129), it is straightforward to check that $M_1$ has the following form

$$M_1 = \begin{bmatrix} \alpha^D(\varepsilon I_q + I_q) & S_x \\ S_x^T & \beta^D(\varepsilon I_q + I_q) \end{bmatrix}, \quad \text{so } \det(M_1) = \left( \prod_{i \in [q]} \alpha_i \right) \left( \prod_{j \in [q]} \beta_j \right) \det(\varepsilon I_q + I_q + J), \quad (130)$$

where $J$ is the matrix in Lemma 35. Note that in Equation (130), to get the second equality, we did the following operations on $M_1$: for $i = 1, \ldots, q$, we divided the $i$-th row of by $\sqrt{\alpha_i}$, the $i$-th column by $\sqrt{\alpha_i}$, the $(i + q)$-th row by $\sqrt{\beta_i}$, the $(i + q)$-th column by $\sqrt{\beta_i}$. The eigenvalues of the matrix $\varepsilon I_q + I_q + J$ are appropriate shifts of the eigenvalues of $J$ and are given by

$$\varepsilon, \varepsilon + 2, \varepsilon + 1 \pm \lambda_1, \ldots, \varepsilon + 1 \pm \lambda_{q-1},$$

c.f., Lemma 35 for the definition of the $\lambda_i$ and their properties. We thus obtain

$$[\varepsilon] \det(\varepsilon T_1 - A_1 (H_{1,x})^{-1} A_1^T) = 2 \prod_{i \in [q]} \alpha_i \prod_{j \in [q]} \beta_j \prod_{i \in [q-1]} (1 - \lambda_i^2). \quad (131)$$
In a completely analogous manner, we can also obtain

\[
\varepsilon \text{Det}(\varepsilon T_{2,y} - A_{2,y}(H_{2,y})^{-1}A_{2,y}^T) = 2 \prod_{i,k \in [q]} \gamma_{ik} \prod_{j,l \in [q]} \delta_{jl} \prod_{i \in [q-1]} (1 - \lambda_i^2)^2 \prod_{i,j \in [q-1]} (1 - \lambda_i^2 \lambda_j^2).
\]

(132)

Note here that the \(\lambda_i\)'s are again the same as in Lemma 35. The more complicated product in (132) is due to the eigenvalues of a Kronecker product. We omit the details since these can be inferred from Lemma 48 which will be stated and proved afterwards. There, the shifting of the eigenvalues is different, but otherwise everything else is the same.

The determinant of the matrix \(M_2\) is quite more complicated to compute due to its more intricate complicate block structure, which requires using Schur's complement formula to handle. The following is proved in Section 4.4.3.1.

\[
\varepsilon^3 \text{Det}(\varepsilon T_2 - A_2(H_2)^{-1}A_2^T) = \frac{4 \Delta^{4q-2}}{(\Delta - 1)^{2q^2}} \prod_{i,j \in [q-1]} (1 - (\Delta - 1)^2 \lambda_i^2 \lambda_j^2) \prod_{i \in [q-1]} (1 - \lambda_i^2)^2.
\]

(133)

Equations (124), (131), (132), (133) deal with the factors in Lemma 46 which are tied to the Hessians of the functions. While these contribute the most interesting factors, some care is needed to deal with the remaining factors. This is accomplished in the following lemma, which is proved in Section 4.4.3.2.

**Lemma 47.** Let \(((A_1)_f, (A_1)_{fs}), ((A_{2,y})_f, (A_{2,y})_{fs}), ((A_2)_f, (A_2)_{fs})\) specify arbitrary full dimensional representations of the spaces \(A_1 x = 0, A_{2,y} y = 0, A_2 [\gamma, \delta, y]^\top = 0\). Then:

\[
\text{Det}((A_1)_{fs})^2 = \text{Det}((A_{2,y})_{fs})^2 = \text{Det}((A_2)_{fs})^2 = 1,
\]

(134)

\[
L((A_1)_f, A_1, T_1) = L((A_{2,y})_f, A_{2,y}, T_{2,y}) = 1/2, \quad L((A_2)_f, A_2, T_2) = 1/4,
\]

(135)

where \(T_1, T_{2,y}, T_2\) are given by (129) and the quantities in (135) are defined in Lemma 46.

We are now ready to finish the proof of Lemma 40.

**Proof of Lemma 40.** Apply Lemma 46 three times to unravel the determinants appearing in Lemmas 41 and 42. Each of the resulting quantities has been computed and appears in one of (124), (131), (132), (133) or Lemma 47. The proof of the lemma is completed with careful but otherwise straightforward substitutions. \(\square\)
4.4.3 Remaining Proofs

4.4.3.1 Details for the Second Moment Determinant

We give here the details of the proof of (133), which gives the determinant of the more intricate matrix $M_2 := \epsilon T_2 - A_2 (H_2)^{-1} A_2^T$. The first step of the computation is the same as in the previous arguments and consists of writing out its block structure and then appropriately normalizing the resulting matrix. Here the normalization is slightly more intricate. The analog of (130) is

$$\text{Det}(M_2) = \text{Det}(H_2') \prod_{i \in [q]} \alpha_i \prod_{j \in [q]} \beta_j \prod_{i,k \in [q]} \gamma_{ik} \prod_{j,l \in [q]} \delta_{jl},$$  \hspace{1cm} (136)

where

$$H_2' = \frac{\Delta}{\Delta - 1} \left[ \begin{array}{cc} \frac{\Delta - 1}{\Delta} I_{4q} - V V^T & V \\ V^T & -\frac{\Delta - 1}{\Delta} W \end{array} \right],$$  \hspace{1cm} (137)

and the matrices $W, V$ are given by

$$W = \frac{1}{\Delta - 1} I_{2q^2} - \left[ \begin{array}{cc} 0 & L \otimes L \\ (L \otimes L)^T & 0 \end{array} \right],$$

$$V = (\oplus_2 \alpha^D)^{-1/2} A_{2q,q^2} (\gamma^D)^{1/2} \bigoplus (\oplus_2 \beta^D)^{-1/2} A_{2q,q^2} (\delta^D)^{1/2}.$$

Equation (136) can be obtained by performing the following operations on $M_2$: for $i = 1, \ldots, q$, divide the $i, i + q$ rows by $\sqrt{\alpha_i}$; for $i = 1, \ldots, q$, divide the $i + q, i + 3q$ rows by $\sqrt{\beta_i}$; for $i, j = 1, \ldots, q$, divide the $4q + q(i - 1) + j$ row by $\sqrt{\gamma_{ij}}$ and the $4q + q^2 + q(i - 1) + j$ row by $\sqrt{\delta_{ij}}$; and the same operations on columns. These operations are captured by the matrices $(\oplus_2 \alpha^D)^{-1/2}$, $(\oplus_2 \beta^D)^{-1/2}$, $(\gamma^D)^{1/2}$, $(\delta^D)^{-1/2}$ which appear in the matrix $V$. The matrix $W$ is the normalized form of $-A_{2,y} (H_{2,y})^{-1} A_{2,y}^T$ but with some corrections in the diagonal which stem from the coupled form of the matrix $A_2$ and the factor $\Delta/\Delta - 1$ which appears in $H_2$, c.f., Equations (122) and (124).

In light of (136), it suffices to compute $\text{Det}(H_2')$. To do this, we proceed by taking the Schur complement of the matrix $W$. For this, we need that $W$ is invertible, as the following lemma guarantees.
Lemma 48. Let \( t = 1/(\Delta - 1) \). In the notation and setting of Lemma 35, the spectrum of \( W \) is given by

\[
t \pm 1, t \pm \lambda_1, t \pm \lambda_1, \ldots, t \pm \lambda_q-1, t \pm \lambda_q-1, t \pm \lambda_1^2, t \pm \lambda_1 \lambda_q-1, t \pm \lambda_2 \lambda_1, \ldots, t \pm \lambda_q \lambda_1.
\]

Recall that the \( \lambda_i \) are non-negative and \( \max \lambda_i < \frac{1}{\Delta-1} \). Hence, \( W \) is invertible. We also have

\[
\det(W) = -\frac{\Delta(\Delta - 2)}{(\Delta - 1)^2} \prod_{i \in [q-1]} (1 - (\Delta - 1)^2 \lambda_i^2)^2 \prod_{i,j \in [q-1]} (1 - (\Delta - 1)^2 \lambda_i^2 \lambda_j^2).
\]

(138)

Proof of Lemma 48. The matrix \( tI_{2q^2} \) shifts the eigenvalues of \( \begin{bmatrix} 0 & L \otimes L \\ (L \otimes L)^T & 0 \end{bmatrix} \) by \( t \), so it suffices to find the eigenvalues of the latter matrix.

These come in pairs \( (\sigma_i^2, -\sigma_i^2) \), \( i \in [q^2] \), where \( \{\sigma_i^2\}_{i \in [q^2]} \) are the singular values of \( L \otimes L \). By properties of the Kronecker Product, these are equal to \( \{(\sigma_i')^2(\sigma_j')^2\}_{i,j \in [q]} \), where \( \{(\sigma_i')^2\}_{i \in [q]} \) are the singular values of \( L \). The latter are the non-negative eigenvalues of \( \begin{bmatrix} 0 & L \\ L^T & 0 \end{bmatrix} \) and are precisely \( \{1, \lambda_1, \ldots, \lambda_{q-1}\} \). The lemma follows.

After taking the Schur complement of the matrix \( W \), we obtain

\[
\det(H'_2) = \left(\frac{\Delta}{\Delta - 1}\right)^{4q} \det(W) \det\left(\varepsilon \frac{\Delta}{\Delta - 1} I_{4q} + Z\right), \text{ with } Z = \frac{\Delta}{\Delta - 1} VW^{-1}V^T - \varepsilon V V^T.
\]

(139)

We are left with the evaluation of \( \det(\varepsilon \frac{\Delta}{\Delta - 1} I_{4q} + Z) \). This is possible once we know the eigenvalues of \( Z \), since the identity matrix just shifts its eigenvalues. The complication here is the nontrivial inverse of \( W \) appearing in the formulation of \( Z \). The next couple of lemmas circumvent the computation of \( W^{-1} \) and reduce it to the inverse of a much simpler matrix.

Lemma 49. In the notation and setting of Lemma 35, it holds that

\[
VW = \left(\frac{1}{\Delta - 1} I_{4q} - L'\right)V, \text{ where } L' = \begin{bmatrix} 0 & L \oplus L \\ (L \oplus L)^T & 0 \end{bmatrix}.
\]
Lemma 49 is useful only if the matrix \( \frac{1}{\Delta - 1}I_{4q} - L' \) is invertible. This is an immediate corollary of the following.

**Lemma 50.** The spectrum of the matrix \( L' \) defined in Lemma 49 is given by

\[
\pm 1, \pm 1, \pm \lambda_1, \pm \lambda_1, \ldots, \pm \lambda_{q-1}, \pm \lambda_{q-1}.
\]

Recall that the \( \lambda_i \) are non-negative and \( \max_i \lambda_i < \frac{1}{\Delta - 1} \). Hence, \( \frac{1}{\Delta - 1}I_{4q} - L' \) is invertible.

**Proof of Lemma 50.** The matrix \( L' \) is similar by a permutation matrix to the direct sum of two copies of the matrix \( J \) of Lemma 35. Thus, the eigenvalues of \( L' \) can be easily derived by properties of the direct sum. The matrix \( \frac{1}{\Delta - 1}I_{4q} \) just shifts the eigenvalues of \(-L'\) by \( 1/(\Delta - 1) \). The lemma follows. \( \square \)

Combining Lemmas 49 and 50, we obtain

\[
Z = \left[-I_{4q} + \frac{\Delta}{\Delta - 1} \left( \frac{1}{\Delta - 1}I_{4q} - L' \right)^{-1} \right]VV^t = (I_{4q} + L') \left( \frac{1}{\Delta - 1}I_{4q} - L' \right)^{-1}VV^t, \quad (140)
\]

By (139), \( Z \) is trivially symmetric. As a consequence of Equation (140), we are now in position to study the eigenvalues of \( Z \).

**Lemma 51.** The spectrum of \( Z \) is given by

\[
0, 0, 0, 2f(1), f(\pm \lambda_1), f(\pm \lambda_1), \ldots, f(\pm \lambda_{q-1}), f(\pm \lambda_{q-1}),
\]

where \( f(x) = (1 + x)(\frac{1}{\Delta - 1} - x)^{-1} \).

To simplify slightly the expressions, set \( r = (\Delta - 1)/\Delta \). The matrix \( \varepsilon r I_{4q} \) shifts the eigenvalues of \( Z \) by \( \varepsilon r \). Thus, Lemma 51 yields

\[
\det(\varepsilon r I_{4q} + Z) = \varepsilon^3 r^3 (\varepsilon r + 2f(1)) \prod_{i \in [q-1]} (\varepsilon r + f(\lambda_i))^2 \prod_{i \in [q-1]} (\varepsilon r + f(-\lambda_i))^2.
\]

By Lemma 51, we have \( f(1), f(\pm \lambda_i) \neq 0 \) for every \( i \in [q-1] \), so that

\[
[\varepsilon^3] \det(\varepsilon r I_{4q} + Z) = 2r^3 f(1) \prod_{i \in [q-1]} (f(-\lambda_i) f(\lambda_i))^2 = -4(\Delta - 1)^4 \frac{1}{\Delta^3 (\Delta - 2)} \prod_{i \in [q-1]} \left( \frac{1 - \lambda_i^2}{1 - (\Delta - 1)^2 \lambda_i^2} \right)^2.
\]

(141)
Plugging (138) and (141) in (139), we obtain

$$\varepsilon^3 \text{Det}(H_2') = \frac{4\Delta^{4q-2}}{(\Delta - 1)^{2q^2}} \prod_{i,j \in [q-1]} (1 - (\Delta - 1)^2 \lambda_i^2 \lambda_j^2) \prod_{i \in [q-1]} (1 - \lambda_i^2)^2.$$  

Using this and (136), we obtain (133).

**Proof of Lemma 51.** Define

\[
\begin{align*}
\mathbf{u}_1 &= [\sqrt{\alpha}, \sqrt{\alpha}, \sqrt{\beta}, \sqrt{\beta}]^\top, & \mathbf{u}_3 &= [\sqrt{\alpha}, 0, -\sqrt{\beta}, 0]^\top, \\
\mathbf{u}_2 &= [\sqrt{\alpha}, -\sqrt{\alpha}, \sqrt{\beta}, -\sqrt{\beta}]^\top, & \mathbf{u}_4 &= [0, \sqrt{\alpha}, 0, -\sqrt{\beta}]^\top,
\end{align*}
\]

and set \( S_1 = \{\mathbf{u}_1, \mathbf{u}_2, \mathbf{u}_3, \mathbf{u}_4\} \) and \( S_2 = \{\mathbf{v} : \mathbf{v} \text{ eigenvector of } L' \text{ with eigenvalue } \mu, |\mu| \neq 1\} \).

We claim that \( S_1 \cup S_2 \) is a linearly independent set of eigenvectors of \( Z \).

Let \( \mathbf{v} \in S_2 \) and let \( \mu \) be the eigenvalue of \( L' \) associated to \( \mathbf{v} \). Then it is easy to check that \( \mathbf{V} \mathbf{V}^\top \mathbf{v} = \mathbf{v} \), so that \( Z \mathbf{v} = f(\mu)\mathbf{v} \). This gives us \( 4(q-1) \) eigenvectors of \( \mathbf{V} \mathbf{V}^\top \) with eigenvalue 1.

Moreover, it is easy to see that

\[
\begin{align*}
[\sqrt{\alpha}, \sqrt{\alpha}, 0, 0]^\top, [0, 0, \sqrt{\beta}, \sqrt{\beta}]^\top, [\sqrt{\alpha}, -\sqrt{\alpha}, 0, 0]^\top, [0, 0, \sqrt{\beta}, -\sqrt{\beta}]^\top
\end{align*}
\]

are linearly independent eigenvectors of \( \mathbf{V} \mathbf{V}^\top \) with eigenvalues 2, 2, 0, 0 respectively.

Using these or by straightforward calculation, we obtain \( \mathbf{V} \mathbf{V}^\top \mathbf{u}_1 = 2\mathbf{u}_1, \mathbf{V} \mathbf{V}^\top \mathbf{u}_2 = 0, \mathbf{V} \mathbf{V}^\top \mathbf{u}_3 = \mathbf{u}_2, \mathbf{V} \mathbf{V}^\top \mathbf{u}_4 = \mathbf{u}_2 \). Noting that \( \mathbf{u}_1, \mathbf{u}_2 \) are eigenvectors of \( L' \) with eigenvalues 1 and -1 respectively, we obtain that the vectors in \( S_1 \) are eigenvectors of \( Z \) with eigenvalues \( 2f(1), 0, 0, 0 \) respectively.

\( \square \)

**Proof of Lemma 49.** For notational convenience, set

\[
\begin{align*}
\mathbf{R} &= (\oplus_2 \alpha^D)^{-1/2} \mathbf{A}_{2q,q^2}(\gamma^D)^{1/2}, & \mathbf{S} &= (\oplus_2 \beta^D)^{-1/2} \mathbf{A}_{2q,q^2}(\delta^D)^{1/2}, & \mathbf{N} &= \mathbf{L} \otimes \mathbf{L}.
\end{align*}
\]

Note that \( \mathbf{V} = \mathbf{R} \oplus \mathbf{S} \). The lemma clearly reduces to proving

\[
\mathbf{R} \mathbf{N} = \begin{bmatrix} \mathbf{L} & 0 \\ 0 & \mathbf{L} \end{bmatrix} \mathbf{S}, \quad \mathbf{S} \mathbf{N}^\top = \begin{bmatrix} \mathbf{L}^\top & 0 \\ 0 & \mathbf{L}^\top \end{bmatrix} \mathbf{R}.
\]

We prove the first of these equalities, since the proof of the latter is identical. Let \( \mathbf{A}, \mathbf{B} \) be the matrices in the lhs and rhs of the equality. \( \mathbf{A}, \mathbf{B} \) clearly have the same dimensions,
easily extends to the more complicated related to the proof of Kirchoff’s Matrix-Tree Theorem, but is written in a way that it is easy to see that their entries are given by

\[
R_{t,(i,k)} = \begin{cases} \sqrt{\frac{\gamma t}{\alpha i}} 1\{i = t\}, & 1 \leq t \leq q \\ \sqrt{\frac{\gamma t}{\alpha k}} 1\{k = t - q\}, & q + 1 \leq t \leq 2q \end{cases},
S_{i,(j,l)} = \begin{cases} \sqrt{\frac{\beta j}{\gamma i}} 1\{j = i\}, & 1 \leq i \leq q \\ \sqrt{\frac{\beta j}{\gamma i}} 1\{l = i - q\}, & q + 1 \leq i \leq 2q \end{cases},
\]

and \(N_{(i,k),(j,l)} = x_{ij}x_{kl}/\sqrt{\gamma ik\delta jl}\). We are now ready to prove that \(A = B\). Consider the \((i,(j,l))\) entries of these matrices. Wlog we may assume \(i \leq q\). We have

\[
A_{i,(j,l)} = \sum_{i',k} R_{i,(i',k)} N_{(i',k),(j,l)} = \sum_{i',k} \sqrt{\frac{\gamma i't}{\alpha i'i}} 1\{i' = i\} \frac{x_{i'j}x_{kl}}{\sqrt{\gamma i'k\delta jl}} = \frac{x_{ij}}{\sqrt{\alpha i}} \sum_{k} x_{kl} = \frac{\beta_j x_{ij}}{\sqrt{\alpha i} \sqrt{\delta jl}}.
\]

\[
B_{i,(j,l)} = \sum_{j'} L_{i,j'} S_{j',(j,l)} = \sum_{j'} L_{i,j'} \sqrt{\frac{\delta jl}{\beta_j}} 1\{j = j'\} = \frac{x_{ij}}{\beta_j} \sqrt{\delta jl}.
\]

Thus \(A_{i,(j,l)} = B_{i,(j,l)}\) for every \(i,j,l\) and we are done. \(\square\)

4.4.3.2 Proof of Lemma 47

We first prove (134). Since \(A_1, A_{2,y}\) are incidence matrices of the bipartite graphs \(G_x, G_y\), they are totally unimodular matrices. By the way full dimensional representations are chosen, the matrices \((A_1)_{fs}, (A_{2,y})_{fs}\) are invertible and hence their determinants squared equal 1. For \((A_2)_{fs}\), the same logic applies: by (122), it is immediate to verify that \((A_2)_{fs}\) has the block decomposition

\[
(A_2)_{fs} = \begin{bmatrix} (A_{2,\gamma \delta})_{fs} & 0 \\ -I & (A_{2,y})_{fs} \end{bmatrix},
\]

so that \(\text{Det}((A_2)_{fs}) = \text{Det}((A_{2,\gamma \delta})_{fs}) \text{Det}((A_{2,y})_{fs})\).

Since \(A_{2,\gamma \delta}, A_{2,y}\) are totally unimodular, any invertible submatrix of them has determinant \(\pm 1\). This concludes the proof of (134).

We next turn to (135). We begin with \(L((A_1)_{f}, A_1, T_1)\). The argument is closely related to the proof of Kirchoff’s Matrix-Tree Theorem, but is written in a way that it easily extends to the more complicated \(L((A_2)_{f}, A_2, T_2)\).

Denote by \(\mu_1, \ldots, \mu_{2q-1}\) the non-zero eigenvalues of \(A_1 A_1^\top\); there are exactly \(2q - 1\) of those since \(G_x\) is a connected bipartite graph. Moreover, \(v_0^\top = \frac{1}{\sqrt{2q}} [-1_q \ 1_q]\) is the unit
eigenvector of $A_1 A_1^\top$ with eigenvalue 0. We claim that

$$[e] \text{Det}(e^T x - A_1 A_1^\top) = -\prod_{i \in [2q-1]} \frac{\mu_i}{q}, \quad \text{Det}((A_1)_f (A_1)_f^\top) = -\prod_{i \in [2q-1]} \frac{\mu_i}{2q}, \quad (142)$$

which clearly proves $L((A_1)_f, A_1, T_1) = 1/2$. The first equality is a direct application of Lemma 44, after observing that $v_0^T T v_0 = 1/q$. The second can be proved as follows. The matrix $(A_1)_f (A_1)_f^\top$ is a principal minor of $A_1 A_1^\top$, the specific principal minor is clearly determined by which row of $A_1$ we chose to delete to obtain $(A_1)_f$. Since $A_1 A_1^\top$ has exactly one zero eigenvalue, we have

$$- \prod_{i \in [2q-1]} \mu_i = \sum_{W \in ([2q]_{q-1})} \text{Det}((A_1)_W (A_1)_W^\top), \quad (143)$$

where $(A_1)_W$ is the submatrix of $A_1$ induced by the rows indexed with $W$. It is easily checked that for any $W, W' \in ([2q]_{q-1})$, there exists a unitary matrix $P$ such that $(A_1)_W = P (A_1)_W'$, so that all summands in (143) are equal. Indeed, since $A$ corresponds to the incidence matrix of a bipartite graph or otherwise, the sum of the first $q$ rows (as vectors) equals the sum of the last $q$ rows. It follows that any row of $A_1$ can be expressed as a $\{1, -1\}$ linear combination of the remaining rows, which easily yields the existence of $P$ with the desired properties. Hence, for any $(A_1)_f$ as in the statement of the Lemma, the second equality in (142) holds as well.

The argument for $L((A_2, y)_f, A_2, y, T_2, y) = 1/2$ is completely analogous. We give a proof sketch for $L((A_2)_f, A_2, T_2) = 1/4$. The matrix $A_2 A_2^\top$ has zero as an eigenvalue by multiplicity three. Denote by $\sigma_1, \ldots, \sigma_{2q^2+4q-3}$ the non-zero eigenvalues of $A_2 A_2^\top$. By looking at the space $z A_2 = 0$, it is easy to derive an orthonormal set of eigenvectors for the eigenvalue 0; these are given by the vectors

$$v_1 = \frac{1}{\sqrt{2q}} [-1_q, 1_q, 0_{2q+2q^2}]^\top, \quad v_2 = \frac{1}{\sqrt{2q}} [0_{2q}, -1_q, 1_q, 0_{2q^2}]^\top, \quad v_3 = \frac{1}{2\sqrt{q + 2q^2}} [-1_{2q}, 1_{2q}, -2_{q^2}, 2_{q^2}]^\top.$$

Moreover, the analog of (143) is

$$- \prod_{i \in [2q^2+4q-3]} \sigma_i = \sum_{W \in ([2q^2+4q-3]_{q-3})} \text{Det}((A_2)_W (A_2)_W^\top). \quad (144)$$

The difference of (144) from (143) is the existence of $W \in ([2q^2+4q]_{2q^2+4q-3})$ which do not contribute to the sum, i.e., $\text{Det}((A_2)_W (A_2)_W^\top) = 0$. We thus restrict our attention to $W$ with non-zero
contribution. These correspond to deleting three rows of $A_2$ such that either (i) all three rows are among the first $4q$ rows of $A_2$, (ii) two of the rows are among the first $4q$ rows of $A_2$ and the remaining is from the last $2q^2$ rows. Note that the deletions must be such that the rank of $A_2$ is preserved. Using the block decomposition of $A_2$, c.f. (122), it can easily be checked that there are $4q^3$ $W$’s of the form (i) and $8q^4$ of the form (ii), for a total of $4q^3(2q + 1)$.

Moreover, it can be seen that all non-zero summands in (143) are equal. This can be proved using the following linear dependencies among the rows of $A_2$: (i) the sum of rows $1, \ldots, q$ is equal to the sum of rows $q+1, \ldots, 2q$, (ii) the sum of rows $2q+1, \ldots, 3q$ is equal to the sum of rows $3q+1, \ldots, 4q$, (iii) the sum of rows $1, \ldots, q-1, q, 4q+1, \ldots, 4q+q^2-1, 4q+q^2$ is equal to the sum of rows $2q+1, \ldots, 3q-1, 3q, 4q + q^2 + 1, \ldots, 4q + 2q^2 - 1, 4q + 2q^2$.

Hence, the equality $L((A_2)_f, A_2, T_2) = 1/4$ is obtained by the following analog of (142)

$$[\varepsilon]\text{Det}(\varepsilon T_2 - A_2 A_2^\top) = -\frac{\prod_{i \in [2q^2 + 4q - 3]} \sigma_i}{q^3(2q + 1)}; \quad \text{Det}((A_2)_f (A_2)_f^\top) = -\frac{\prod_{i \in [2q^2 + 4q - 3]} \sigma_i}{4q^3(2q + 1)}.$$
CHAPTER V

NP-HARDNESS FOR COUNTING IN ANTIFERROMAGNETIC MODELS

In this chapter, we are going to prove Theorem 14, which we recall for convenience here.

**Theorem 14.** Let $q \geq 2$, $\Delta \geq 3$. For an antiferromagnetic $q$-spin system with interaction matrix $B$, if the dominant semi-translation invariant Gibbs measures on the tree $T_\Delta$ are permutation symmetric and all of them are Hessian dominant and not translation invariant then, unless $\text{NP}=\text{RP}$, there is no FPRAS for approximating the partition function for triangle free $\Delta$-regular graphs. Moreover, there exists $\varepsilon = \varepsilon(q, \Delta)$ such that, unless $\text{NP}=\text{RP}$, one cannot approximate the partition function within a factor $2^{\varepsilon n}$ for triangle-free $\Delta$-regular graphs (where $n$ is the number of vertices).

We begin with a more thorough overview of antiferromagnetic spin systems.

5.1 Antiferromagnetic Spin Systems

In this section, we define antiferromagnetic models in terms of the eigenvalues of the interaction matrix $B$. Using this definition, we then state and prove properties of antiferromagnetic models relevant to this work.

The interaction matrix $B$ is assumed to be symmetric and have non-negative entries. These are standard assumptions since we are interested in undirected graphs and the Gibbs distribution should be a probability distribution. We will also assume that $B$ is primitive, i.e., irreducible and aperiodic. As we demonstrate next, this is also a natural restriction which does not affect generality.

If $B$ is reducible, by a suitable permutation of the labels of colors, $B$ can be put into block diagonal form (which coincides with the normal form of the reducible $B$) where each of the blocks is either irreducible or zero. Intuitively, this says that the original spin model can be studied by considering the induced sub-models of each block which correspond to
irreducible symmetric matrices (where our results apply). Indeed, these sub-models are “non-interacting” for connected graphs $G$, that is, the partition function for the original model is simply the sum of the partition functions of each sub-model.

We are now ready to give the definition of antiferromagnetism we use.

**Definition 10.** Let $B$ be the interaction matrix of a $q$-state spin system. Since $B$ is symmetric all of its eigenvalues are real. Also note that it has non-negative entries and by irreducibility, the Perron-Frobenius theorem implies that one of the eigenvalues of $B$ with the largest magnitude is positive and simple, i.e., the associated eigenspace is one-dimensional. The model is called antiferromagnetic if all the other eigenvalues are negative. Note that no eigenvalue is allowed to be zero and hence $B$ is regular.

The above definition generalizes antiferromagnetism for 2-spin systems, and captures colorings as well as the antiferromagnetic region for the Potts models. Moreover, the above definition seems natural in that it implies that neighboring vertices prefer to have different spin assignments (see Corollary 53 below). Another nice feature of Definition 10 is that it does not depend on the presence of external fields. Specifically, for $\Delta$-regular graphs, any external field can be pushed into the interaction matrix $B$ with a congruence transformation of the matrix $B$. The resulting interaction matrix, by Sylvester’s law of inertia, has the same number of positive, zero and negative eigenvalues and in particular remains antiferromagnetic.

We conclude this discussion by pointing out that some of our results for general models are more easily stated when $B$ is further assumed to be aperiodic. We shall refer to such matrices $B$ (irreducible and aperiodic) as ergodic. Note that if $B$ is periodic, its period must be two, since $B$ is symmetric. Such a model is only interesting on bipartite graphs (otherwise the partition function is zero). It can be verified that Definition 10 of antiferromagnetism implies that the matrix $B$ is ergodic whenever $q \geq 3$ (note that it is trivial to compute the partition function on periodic models with $q = 2$).
5.1.1 Properties

As a consequence of the Perron-Frobenius theorem and the antiferromagnetism definition, we may decompose the interaction matrix $B$ of an antiferromagnetic model as

$$B = uu^T - P^T P,$$

(145)

where the vector $u$ has positive entries and $P$ is a square matrix. Using the decomposition (145), we prove the following two lemmas which are used in the reduction.

**Lemma 52.** For antiferromagnetic $B$, and vectors $z_1, z_2 \in \mathbb{R}_{\geq 0}^q$ with $\|z_1\|_1 = \|z_2\|_1 = 1$, we have

$$(z_1^T B z_1) (z_2^T B z_2) \leq (z_1^T B z_2)^2.$$  

Equality holds iff $z_1 = z_2$.

**Proof.** Set $w_1 = Pz_1$, $w_2 = Pz_2$, $a_1 = u^T z_1$, $a_2 = u^T z_2$. Then

$$z_1^T B z_1 = a_1^2 - w_1^T w_1, \quad z_2^T B z_2 = a_2^2 - w_2^T w_2, \quad z_1^T B z_2 = a_1 a_2 - w_1^T w_2.$$  

Since $B, z_1, z_2$ have nonnegative entries, the above equalities imply $a_1^2 - w_1^T w_1, a_2^2 - w_2^T w_2, a_1 a_2 - w_1^T w_2 \geq 0$. The inequality reduces to

$$(a_1^2 - w_1^T w_1)(a_2^2 - w_2^T w_2) \leq (a_1 a_2 - w_1^T w_2)^2.$$  

This is known as Aczél’s inequality. The fastest proof goes as follows: set $b_1^2 = a_1^2 - w_1^T w_1$ and $b_2^2 = a_2^2 - w_2^T w_2$, so that by Cauchy-Schwarz $a_1 a_2 \geq b_1 b_2 + w_1^T w_2$, implying the inequality.

Equality can only hold if $a_1 = \lambda a_2$ and $w_1 = \lambda w_2$, yielding $u^T (z_1 - \lambda z_2) = 0$ and $P(z_1 - \lambda z_2) = 0$. We easily obtain $B(z_1 - \lambda z_2) = 0$ and since $B$ is invertible, $z_1 = \lambda z_2$. The assumption $\|z_1\|_1 = \|z_2\|_1 = 1$ implies $\lambda = 1$, as wanted.

**Corollary 53.** By plugging in the inequality of Lemma 52 the vectors with a single 1 in the positions $i$ and $j$ respectively, we obtain that any two spins $i, j$ induce an antiferromagnetic two-spin system.

**Lemma 54.** Let $z_1, \ldots, z_n \in \mathbb{R}^d$ be a collection of distinct non-negative vectors such that $\|z_i\|_1 = 1$ for $i \in [n]$. Let $a_i = z_i^T u$, where $u$ is as in (145). Let $A'$ be the $n \times n$ matrix whose $ij$-th entry is $\ln(z_i^T B z_j) - \ln(a_i) - \ln(a_j)$. Then $A'$ is negative definite.
Proof. Let \( w_i = \frac{1}{a_i} \mathbf{P} z_i \) and let \( \mathbf{W} \) be the \( q \times n \) matrix whose columns are \( w_1, \ldots, w_n \). We first argue \( w_i \neq w_j \) for \( i \neq j \). Suppose \( w_i = w_j \). Let \( z = \frac{1}{a_i} z_i - \frac{1}{a_j} z_j \). We have \( \mathbf{P} z = w_i - w_j = 0 \) and \( u^\top z = 1 - 1 = 0 \) and hence \( \mathbf{B} z = 0 \). Since \( \mathbf{B} \) is regular we have \( z = 0 \). Thus \( 0 = z^\top \mathbf{1} = \frac{1}{a_i} - \frac{1}{a_j} \) which implies \( a_i = a_j \) which in turn implies \( z_i = z_j \), a contradiction. Thus \( w_i \neq w_j \) for \( i \neq j \).

Note that we have

\[
\ln(1 - w_i^\top w_j) = \ln(a_i a_j - z_i^\top \mathbf{P}^\top \mathbf{P} z_j) - \ln(a_i a_j) = A_{ij}'.
\]

Thus the \( ij \)-th entry in \( \mathbf{A}' \) is obtained by applying \( z \mapsto \ln(1 - z) \) to each entry of the Gramm matrix \( \mathbf{W}^\top \mathbf{W} \). Note that for \( |z| < 1 \) we have \( \ln(1 - z) = -z - z^2/2 - z^3/3 - \ldots \) and hence by Schur product theorem \( \mathbf{A}' \) is negative semi-definite (see Corollary 7.5.9 in [23]).

Now we argue that \( \mathbf{A}' \) is regular (and hence negative definite). We have

\[
-A' = \sum_{k=1}^{\infty} \frac{1}{k} \mathbf{W}_k^\top \mathbf{W}_k, \tag{146}
\]

where \( \mathbf{W}_k \) is the \( q^k \times n \) matrix whose columns are \( w_1^\otimes k, \ldots, w_n^\otimes k \). Note that if \( \mathbf{A}' \) is singular then there exists a non-zero vector \( v \) such that \( v^\top \mathbf{A}' v = 0 \) and for this to happen we would have to have

\[
\mathbf{W}_k v = 0 \tag{147}
\]

for all \( k \geq 1 \) (the terms on the right-hand side of (146) are non-negative and if even one of them is positive then \( v^\top \mathbf{A}' v < 0 \)).

There exists a vector \( \mathbf{r} \in \mathbb{R}^q \) such that \( a_i = \mathbf{r}^\top \mathbf{w}_i, i = 1, \ldots, n \) are distinct real numbers (the \( \mathbf{w}_i \)'s are distinct and hence for any \( i \neq j \) the measure of \( r \in [0,1]^q \) such that \( \mathbf{r}^\top \mathbf{w}_i = \mathbf{r}^\top \mathbf{w}_j \) is zero). Note that \( (\mathbf{r}^\otimes k)^\top \mathbf{W}_k \) is \( (\alpha_1^k, \ldots, \alpha_n^k) \). From (147) we obtain that for every integer \( k \geq 1 \) we have \( (\alpha_1^k, \ldots, \alpha_n^k) v = 0 \) and hence \( v = 0 \) (by considering the Vandermonde matrix \( \{a_i^k\} \)), a contradiction. Hence \( \mathbf{A}' \) is regular and negative definite.

\[
\Box
\]

### 5.2 The Phase Labeling Problem and a Reduction Scheme

Recall the properties of the gadget from Chapter 4.
Theorem 31. Suppose that the interaction matrix $B$ satisfies hypotheses (H1) and (H2). Let $r$ be a fixed constant. Then, for every $\varepsilon > 0$, a random graph $G \sim G^r_n$ satisfies with probability $1 - o(1)$ as $n \to \infty$ all of the following:

1. For each $p \in Q$, $(1 - \varepsilon)/|Q| \leq \mu_G(Y(\sigma) = p) \leq (1 + \varepsilon)/|Q|$. That is, the phases in $Q$ appear with roughly equal probability.

2. For each $p \in Q$, for all $\eta : W \to [q]$, $\mu_G(\sigma_W = \eta | Y(\sigma) = p)/\nu^p(\eta) \in [1 - \varepsilon, 1 + \varepsilon]$. That is, conditioned on the phase $p$ of the configuration, the spins of the vertices in $W$ are roughly independent and the marginal measure on them can be approximated by the measure $\nu^p(\cdot)$.

3. There is no edge between $W^+$ and $W^-$. Moreover, there is no vertex in $G$ which has two neighbors in $W^+ \cup W^-$. Moreover, $G$ is simple with asymptotically positive probability and the above continue to hold with probability $1 - o(1)$ conditioned on $G$ being simple.

From hereon, we are going to assume that we have a list of the global maxima. Indeed, for fixed $q, \Delta, B$ they can be found using existential theory of reals and can be approximated to any desired polynomial accuracy of their values. Let $Q'$ be the list of the global maxima—we will call them unordered phases and view them as unordered pairs of vectors:

$$Q' = \{(x_1, y_1), \ldots, (x_{Q'}, y_{Q'})\}.$$ 

The assumption of Theorem 14 translates into $x_i \neq y_i$ for all $i \in [Q']$.

Given a phase $\{x_1, y_1\}$ an ordering of the pair will be called “assigning spin to the phase”. Let

$$Q = \{(x_1, y_1), \ldots, (x_Q, y_Q)\}$$

be the collection of ordered phases. Note that $Q = 2Q'$. We will denote unordered phases using $p$; the two ordered phases corresponding to the unordered phase $p$ will be denoted by $p^+$ and $p^-$. Given a graph $H$ with vertex set $V$ we will assign ordered phases to its vertices—the labeling (called phase assignment) will be denoted by $Y : V \to Q$. The
corresponding labeling by unordered phases (where the ordering is removed) will be denoted by \( \mathcal{Y}' \).

Now we define the weight of a phase assignment. We will have two types of edges in \( H \): parallel or symmetric; the type of an edge will only impact the weight of a phase assignment. In particular, a parallel edge whose endpoints have labels \((x_1, y_1)\) and \((x_2, y_2)\) incurs weight

\[
wp((x_1, y_1), (x_2, y_2)) = \ln(x_1^\top B x_2) + \ln(y_1^\top B y_2),
\]

while a symmetric edge incurs weight

\[
w_s((x_1, y_1), (x_2, y_2)) = wp((x_1, y_1), (x_2, y_2)) + wp((x_1, y_1), (y_2, x_2)).
\]

Note that if we flip \((x_1, y_1)\), that is, replace it by \((y_1, x_1)\), the weight of the symmetric edge does not change.

We will use the following problem in our reduction.

**Phase Labeling Problem**\((B, Q)\):

**INPUT:** undirected edge-weighted multigraph \( H = (V, E) \) and a partition of the edges \( \{E_p, E_s\} \).

**OUTPUT:** \( \text{MAXLWT}(H) := \max_{\mathcal{Y}} \text{LWT}_H(\mathcal{Y}) \), where the maximization is over all possible phase labelings \( \mathcal{Y} : V \to Q \) and

\[
\text{LWT}_H(\mathcal{Y}) = \sum_{\{u, v\} \in E_s} w_s(\mathcal{Y}(u), \mathcal{Y}(v)) + \sum_{\{u, v\} \in E_p} w_p(\mathcal{Y}(u), \mathcal{Y}(v)).
\]

The motivation for the **Phase Labeling problem** is the following lemma. The proof roughly follows the lines of [50] and is given in Section 5.3.

**Lemma 55.** In the setting of Theorem 14, the following holds. A (randomized) algorithm that approximates the partition function on triangle free \( \Delta \)-regular graphs within an arbitrarily small exponential factor yields a PRAS for the phase labeling problem with parameters \( B, Q \) on bounded degree graphs.

The most difficult part of our arguments is the following lemma which is given in Section 5.3.1.
Lemma 56. A PRAS for the phase labeling problem with parameters \( B, Q \) on bounded degree graphs yields a PRAS for MaxCut on 3-regular graphs within a factor of \( 1 - o(1) \).

Using Lemmas 55 and 56, we obtain Theorem 14.

Proof of Theorem 14. Suppose that there exists a (randomized) algorithm to approximate the partition function on \( \Delta \)-regular graphs with interaction matrix \( B \) up to an arbitrarily small exponential factor. Then, combining Lemmas 55 and 56, we obtain a (randomized) algorithm to approximate MaxCut on 3-regular graphs within a factor of \( 1 - o(1) \). This contradicts the result of [1]. \( \square \)

5.3 Connection between approximating the partition function and the phase labeling problem

The purpose of this section is to prove Lemma 55.

We begin by clarifying what degree means in our setting. Let \( H = (V, E, w) \) be an instance of the phase labeling problem, where \( \{E_p, E_s\} \) is a partition of the edges and \( |V| = m \). The degree of a vertex \( v \in V \) will be defined as \( 2d_s + d_p + 4l_s + 2l_p \), where \( d_s, d_p \) are the numbers of symmetric and parallel edges joining \( v \) to a distinct vertex \( u \) and \( l_s, l_p \) are the numbers of symmetric and parallel loops from \( v \) to itself. The bounded degree assumption means there is an absolute constant \( D \) (not depending on \( m \)) which bounds the degree of any \( v \in V \).

To approximate the phase labeling problem on \( H \) with parameters \( B, Q \), we will replace each vertex in the graph \( H \) by a suitable graph in a family of gadgets \( F \). The construction has a parameter \( k \) which roughly controls the accuracy of the approximation we want to achieve. The family \( F \) will be of the form \( \{G^d\}_{d \in [D]} \) and the gadget for a vertex \( v \) will be \( G^d \) where \( d \) is the degree of \( v \). Note that the cardinality of \( F \) is bounded by the absolute constant \( D \). The gadgets \( G^d \) are selected from a graph distribution \( \mathcal{G}_{n}^{kd} \) for some appropriate \( n \) to be specified later.

Before further specifying the family \( F \), we first describe the properties that a gadget in \( F \) should have. For this exposition, we assume that \( r \) is an arbitrarily large constant.
Lemma 31 is proved in Section 4.2. An immediate consequence of Lemma 31 is the following.

**Corollary 57.** Let \( k \) be an arbitrarily large constant. For \( d \in [D] \), let \( G^d \sim G^d_n \) and set \( \mathcal{F} = \{G^d\}_{d \in [D]} \). Then, for all sufficiently large \( n \), \( G^d \) is simple and satisfies Items 1, 2 and 3 of Theorem 31 with positive probability for every \( d \in [D] \).

Corollary 57 also yields a trivial randomized algorithm to construct the family \( \mathcal{F} \) for an arbitrary constant \( k \). In fact, since all the parameters are constants, one can construct the family \( \mathcal{F} \) by brute force search. With the family \( \mathcal{F} \) in our hands, we can now give the details of the construction.

The first step consists of replacing each vertex \( v \in H \) with degree \( d \) with a distinct copy of the gadget \( G^d \in \mathcal{F} \). We will refer to the gadget corresponding to vertex \( v \) as \( G_v \) and the respective sets in \( G_v \) as \( W_v, W^\pm_v, U^\pm_v \). Denote by \( \widehat{H} \) the graph obtained by the disconnected copies of the gadgets.

The second step consists of placing the edges of \( H \) in \( \widehat{H} \), that is, making connections between the gadgets. The final graph will be denoted as \( H_{\mathcal{F}} \). The edges we are going to place will form a perfect matching on \( \cup_{v \in H} W_v \) and as a result \( H_{\mathcal{F}} \) will be \( \Delta \)-regular. Every parallel edge of \( H \) corresponds to \( 2k \) edges in \( H_{\mathcal{F}} \), while every symmetric to \( 4k \). Roughly, parallel and symmetric indicate which parts of two gadgets get connected (recall that the gadgets are bipartite). Loops are treated as if they were connecting distinct vertices.

In detail, let \((u, v)\) be an edge \( e \) of \( H \). Suppose first that \( u \neq v \). If \( e \) is parallel, place \( k \) edges between \( W_u^s \) and \( W_v^s \) for \( s \in \{+, -\} \). If \( e \) is symmetric, place \( k \) edges between \( W_u^s \) and \( W_v^s \) and \( k \) edges between \( W_u^s \) and \( W_v^{-s} \) for \( s \in \{+, -\} \). Suppose now that \( u = v \). If \( e \) is parallel, place \( k \) edges between distinct vertices in \( W_v^+ \) and \( k \) edges between distinct vertices in \( W_v^- \). If \( e \) is symmetric, place \( 2k \) edges between \( W_v^+ \) and \( W_v^- \), \( k \) edges between distinct vertices in \( W_v^+ \) and \( k \) edges between distinct vertices in \( W_v^- \).

The first step of the construction guarantees that the second step can be done in a (deterministic) way so that \( H_{\mathcal{F}} \) is \( \Delta \)-regular. Moreover, by Corollary 57 and item 3 of Lemma 31, \( H_{\mathcal{F}} \) is a simple, triangle-free graph.
Proof of Lemma 55. The argument in [50, Lemma 4.3] almost verbatim gives

\[
(1 - \varepsilon)^{2m} \leq \frac{Z_{H^x}/Z_{\hat{H}}}{\exp(k \cdot \text{MAXLWT}(H))} \leq (1 + \varepsilon)^m.
\]

This can be rearranged into

\[
\frac{1}{k} \log \left( \frac{Z_{H^x}}{Z_{\hat{H}}} \right) - \frac{m}{k} \log(1 + \varepsilon) \leq \text{MAXLWT}(H) \leq \frac{1}{k} \log \left( \frac{Z_{H^x}}{Z_{\hat{H}}} \right) - \frac{2m}{k} \log \left( \frac{1 - \varepsilon}{|Q|} \right).
\]

The argument in [50, Proof of Theorems 1 and 2] gives the desired result. We give the short details. The graph \(\hat{H}\) consists of \(m\) disconnected subgraphs, each of constant size. Hence, we can compute \(Z_{\hat{H}}\) exactly in polynomial time. Assume now that \(Z_{H^x}\) can be approximated within a factor of \(\exp(c|\hat{H}|)\) in polynomial time for any \(c > 0\). Since \(\log (Z_{H^x})\) is bounded above by \(O(|\hat{H}|)\), the ratio \(\log (Z_{H^x}/Z_{\hat{H}})\) can be approximated within an additive \(O(c|\hat{H}|) = O(cm(n + kD)) = O(cn m)\) since \(n > kD\). Thus we obtain upper and lower bounds for \(\text{MAXLWT}(H)\) which differ by \(O((cn + 1)m/k)\). A random phase labeling yields the lower bound \(\text{MAXLWT}(H) \geq \Omega(m)\). Thus, the final approximation is within a multiplicative factor \(O((cn + 1)/k)\) of \(\text{MAXLWT}(H)\). Taking \(k\) large and \(c\) small allows to make the multiplicative factor arbitrarily small, as desired. \(\square\)

5.3.1 Reducing MaxCut to Phase Labeling

In this section, we prove the following lemma.

The remainder of this section is devoted to the proof of Lemma 56. We will use the existence of the following gadget which “prefers” the unordered phase of two vertices to agree. We postpone the proof to Section 5.3.2.

Lemma 58. A constant sized gadget \(J_1\) with two special vertices \(u, v\) can be constructed with the following property: all edges of \(J_1\) are symmetric and the following is true,

\[
\max_{\mathcal{Y}; \mathcal{Y}'(u) = \mathcal{Y}'(v)} \text{LWT}_{J_1}(\mathcal{Y}) > \varepsilon_1 + \max_{\mathcal{Y}; \mathcal{Y}'(u) \neq \mathcal{Y}'(v)} \text{LWT}_{J_1}(\mathcal{Y}),
\]

where \(\varepsilon_1 > 0\) is a constant depending only on the spin model and \(\Delta\).

In Section 5.1, Lemma 52 we prove that for a parallel edge and any phase \(p\) we have \(w(p^+, p^+) = w(p^-, p^-) < w(p^+, p^-)\) and hence there exists a constant \(\varepsilon_2 > 0\) depending
only on the model and $\Delta$ such that for every phase $p \in Q$ we have
\[
w_p(p^+, p^+) = w_p(p^-, p^-) < w_p(p^+, p^-) - \varepsilon_2.
\] (149)

Combining Lemma 58 with equation (149) we can construct a gadget that “prefers” the unordered phase of two vertices to agree and also “prefers” the spin assignment to disagree.

**Lemma 59.** A constant sized gadget $J_2$ can be constructed with two special vertices $u, v$ and the following property: there exists a phase $p \in Q'$ satisfying simultaneously all of the following:

1. $A_1(p) = \text{MAXLwt}(J_2)$, where
   \[
   A_1(p) := \max_{Y; Y(u)=p^+, Y(v)=p^-} \text{Lwt}_J(Y) = \max_{Y; Y(u)=p^-, Y(v)=p^+} \text{Lwt}_J(Y). \tag{150}
   \]

2. Among $p$ that satisfy Item 1, $p$ maximizes
   \[
   A_2(p) := \max_{Y; Y(u)=p^+, Y(v)=p^+} \text{Lwt}_J(Y) = \max_{Y; Y(u)=p^-, Y(v)=p^-} \text{Lwt}_J(Y). \tag{151}
   \]

3. The following inequalities hold
   \[
   A_1(p) > A_2(p) + \varepsilon_3 \quad \text{and} \quad A_2(p) > \varepsilon_3 + \max_{Y; Y(u)\neq Y(v)} \text{Lwt}_J(Y), \tag{152}
   \]

where $\varepsilon_3 > 0$ is a constant (depending only on the model and $\Delta$).

**Proof.** To construct $J_2$ we take $t := 3[(\max_{p_1, p_2} w_p(P_1, P_2) - \min_{p_1, p_2} w_p(P_1, P_2))/\varepsilon_1]$ copies of gadget $J_1$ from Lemma 58, identify (merge) their $u$ vertices, and identify (merge) their $v$ vertices. Finally we add a parallel edge between $u$ and $v$.

Let $p$ be the unordered phase that is the common value of $Y'(u)$ and $Y'(v)$ for which the maximum on the left-hand side of (148) is achieved (note that $p$ is not unique; we just take one such $p$). Let

\[
A_4 := \max_{Y; Y'(u)=p, Y'(v)=p} \text{Lwt}_J(Y) \quad \text{and} \quad A_5 := \max_{Y; Y'(u)\neq Y'(v)} \text{Lwt}_J(Y).
\]
Then applying (148) on each copy of $J_1$ in $J_2$ we obtain

$$A_4 > A_5 + 2(\max_{p_1, p_2} w_p(p_1, p_2) - \min_{p_1, p_2} w_p(p_1, p_2)).$$  \quad (153)$$

Thus the maximizer of $\max_Y \text{Lwt}_J(Y)$ happens for $Y$ with $Y'(u) = Y'(v)$. Only the parallel edge is influenced by the spin and hence, by (149), we have

$$\max_Y \text{Lwt}_J(Y) = \max_p \max_{Y : Y(u) = p^+, Y(v) = p^-} \text{Lwt}_J(Y).$$  \quad (154)$$

Let $p$ be the maximizer on the right-hand side of (154) that (secondarily) maximizes the second expression in (151). Note that $p$ satisfies the first and second condition of the lemma.

The first part of the third condition is satisfied for any $\varepsilon_3 \leq \varepsilon_2$ (using (149)). Recall that $\varepsilon_2 > 0$. The second part of the third condition is satisfied for $\varepsilon_3 \leq \max_{p_1, p_2} w_p(p_1, p_2) - \min_{p_1, p_2} w_p(p_1, p_2)$. Recall that $\max_{p_1, p_2} w_p(p_1, p_2) - \min_{p_1, p_2} w_p(p_1, p_2) > 0$. Thus we can take $\varepsilon_3 > 0$ to be the smaller of the two upper bounds (each of which is a constant depending on the model and $\Delta$ only). \hfill $\Box$

**Lemma 60.** Let $B$ be the interaction matrix of an anti-ferromagnetic spin model. Let $A_1, A_2$ be the constants defined in Lemma 59. There exists constants $D_1, D_2, D_3$ depending only on the model and $\Delta$ such that the following is true. Given a cubic graph $H$ we can, in polynomial-time, construct a max-degree-$D_1$ graph $G$ with $|V(G)| \leq D_2|V(H)|$ such that

$$\text{MaxLwt}(G) = (A_1 - A_2)\text{MaxCut}(H) + A_2|E(H)| + A_1D_3|V(H)|.$$

We can now go back and prove the inapproximability result for the phase labeling problem.

**Proof of Lemma 56.** Since $A_1, A_2, D_3$ are constants depending only on the model and $\Delta$, the trivial algorithm gives the bound $\text{MaxCut}(H) \geq 1/2|E(H)| = 3/2|V(H)|$. Together with Lemma 60 we obtain the result. \hfill $\Box$

**Proof of Lemma 60.** Replace each edge of $H$ by gadget $J_2$ and for each vertex $w \in V(H)$ add $D_3$ new vertices $w_1, \ldots, w_{D_3}$ and add a gadget $J_2$ between $w$ and $w_i$ (for $i \in [D_3]$), where $D_3$ will be determined shortly.
The purpose of the $D_3$ copies of $J_2$ is to force phase $p$ (from Lemma 59) to be used on the special vertices in a labeling of $G$ with maximum weight. A phase $r \neq p$ can have

$$
\ell_1(r) := \max_{y; y(u) = r^+, y(v) = r^+} \text{LWT}_{J_2}(y) - \max_{y; y(u) = p^+, y(v) = p^+} \text{LWT}_{J_2}(y) > 0, \quad (155)
$$

but then by the choice of $p$

$$
\ell_2(r) := \max_{y; y(u) = p^+, y(v) = p^-} \text{LWT}_{J_2}(y) - \max_{y; y(u) = r^+, y(v) = r^-} \text{LWT}_{J_2}(y) > 0. \quad (156)
$$

Let

$$
D_3 = 4 + 3 \left[ \max_r \frac{\ell_1(r)}{\ell_2(r)} \right],
$$

where the maximum is taken over $r$ such that (155) is satisfied (if no such $r$ exists we can take $D_3 = 0$). Note that $D_3$ is a constant depending on the model and $\Delta$ only.

Now we want to find the maximum weight labeling of $G$. We are only going to focus on labeling of the special vertices ($u$’s and $v$’s in the $J_2$ gadgets), since once those are fixed one just finds the optimal labeling in each gadget (conditioned on the labels of special vertices).

Let $W$ be a labeling of the special vertices that leads to the maximum weight labeling of $G$. Let $\hat{W}$ be the labeling obtained from $W$ by changing the phase of each special vertex to $p$ while (1) keeping the original spin on the vertices of $H$, and (2) making the spin of $w_1, \ldots, w_{D_3}$ the opposite of the spin of $w$ (for each $w \in V(H)$). Now we compare $W$ and $\hat{W}$ for each $J_2$ gadget corresponding to edge of $H$:

- if in $W$ the phase of $u$ and $v$ were different then $\hat{W}$ has higher weight than $W$ on the gadget, using (152);

- if in $W$ the phase of $u$ and $v$ is the same but the spin is different then $\hat{W}$ has greater or equal weight than $W$ on the gadget, using (150);

- if in $W$ the phase of $u$ and $v$ is the same and the spin is the same that the loss of $\hat{W}$ on the gadget (compared to $W$) is $\ell_1(r)$ (where $r$ is the phase of $u$, $v$ in $W$).

For the $J_2$ gadgets connecting $w$ to $w_1, \ldots, w_{D_3}$ we have

- if the phase of $w$ in $W$ was $r$ such that $\ell_1(r) > 0$ then the gain of $\hat{W}$ on each gadget (compared to $W$) is at least $\ell_2(r)$;
For each vertex whose phase in $W$ was $r$ such that $\ell_1(r) > 0$ there are 3 edges where $\hat{W}$ can lose $\ell_1(r)$ (compared to $W$) but there are $D_3$ edges where $\hat{W}$ gains $\ell_2(r)$ (compared to $W$). Since $D_3\ell_2(r) > 3\ell_1(r)$ we have that $\hat{W}$ has at least as large weight as $W$ (and hence is also optimal).

Now we just argue how the spins should be assigned. The largest number of $J_2$ gadgets with opposite spins on the special vertices arises when we take the max-cut of $H$ and assign the spin according to the cut.

5.3.2 The gadget

Proof of Lemma 58. Let $z_1, \ldots, z_Q := x_1, \ldots, x_{Q'}, y_1, \ldots, y_{Q'}$. Let $u$ be defined as in Equation (145). In Section 5.1, Lemma 54 it is proved that the $Q \times Q$ matrix $\hat{A}$ whose $ij$-th entry is $\ln(z_i^\top Bz_j) - \ln(z_i^\top u) - \ln(z_j^\top u)$ is negative definite. Let $A'$ be the $Q' \times Q'$ matrix obtained by the following “folding” of $\hat{A}$:

$$A'_{ij} = \hat{A}_{i,j} + \hat{A}_{i+Q',j} + \hat{A}_{i,j+Q'} + \hat{A}_{i+Q',j+Q'}.$$  

We have that $A'$ is also negative definite (since $x^\top A'x = y^\top \hat{A}y'$, where $y^\top = (x^\top, x^\top)$).

Note that

$$A'_{ij} = w_s((x_i, y_i), (x_j, y_j)) - a'_i - a'_j,$$

where $a'_i := 2\ln(x_i^\top u) + 2\ln(y_i^\top u)$.

Let $\lambda_1$ be largest eigenvalue of $-A'$ and let $\lambda_2$ be the smallest eigenvalue of $-A'$. Note that $0 < \lambda_2 \leq \lambda_1$. Define $A$ to be the $Q' \times Q'$ matrix with $A_{ij} = A'_{ij} + a'_i + a'_j$ and consider the following maximization problem

$$\max_{x: x^\top 1 = 1, x \geq 0} x^\top Ax.$$  \hspace{1cm} \text{(157)}

Note that for $x$ with $x^\top 1 = 1$ we have

$$x^\top Ax = 2a'^\top x + x^\top A'x,$$  \hspace{1cm} \text{(158)}

where $A'$ is negative definite. Note that if $x$ and $y$ are distinct optimal solutions of (157) then $(x + y)/2$ satisfies all the constraints, and from (158) and negative definiteness of $A'$
we have

\[(\mathbf{x} + \mathbf{y})/2)^\top \mathbf{A}((\mathbf{x} + \mathbf{y})/2) > (\mathbf{x}^\top \mathbf{A}\mathbf{x} + \mathbf{y}^\top \mathbf{A}\mathbf{y})/2,\]

a contradiction (with optimality of both \(x\) and \(y\)). Thus (157) has a unique maximum; let \(\mathbf{x}^*\) be the value of \(\mathbf{x}\) achieving it. Let \(O^*\) be \((\mathbf{x}^*)^\top \mathbf{A}\mathbf{x}^*\). Let \(S\) be the set of non-zero coordinates in \(\mathbf{x}^*\).

Let \(\mathbf{y} \in \mathbb{R}^{Q'}\) be such that \(\mathbf{y}^\top \mathbf{1} = 0\) and \(\mathbf{y}\) is zero on coordinates outside \(S\). Then from (local) optimality of \(\mathbf{x}^*\) we have

\[(\mathbf{x}^* + \mathbf{y})^\top \mathbf{A}(\mathbf{x}^* + \mathbf{y}) = O^* + 2(\mathbf{a}^\top + (\mathbf{x}^*)^\top \mathbf{A'})\mathbf{y} + \mathbf{y}^\top \mathbf{A'}\mathbf{y} = O^* + \mathbf{y}^\top \mathbf{A'}\mathbf{y} \geq O^* - \lambda_1 \|\mathbf{y}\|_2^2. \tag{159}\]

Equation (159) tells us that moving slightly from the optimum the objective decreases at most quadratically in the length of \(\mathbf{y}\).

Let \(\mathbf{y} \in \mathbb{R}^{Q'}\) be such that \(\mathbf{y}^\top \mathbf{1} = 0\) and \(\mathbf{y}\) is non-negative on coordinates outside \(S\). Then from (local) optimality of \(\mathbf{x}^*\) we have

\[(\mathbf{x}^* + \mathbf{y})^\top \mathbf{A}(\mathbf{x}^* + \mathbf{y}) = O^* + 2(\mathbf{a}^\top + (\mathbf{x}^*)^\top \mathbf{A'})\mathbf{y} + \mathbf{y}^\top \mathbf{A'}\mathbf{y} = O^* + \mathbf{y}^\top \mathbf{A'}\mathbf{y} \geq O^* - \lambda_2 \|\mathbf{y}\|_2^2. \tag{160}\]

Equation (159) tells us that moving slightly from the optimum the objective decreases at least quadratically in the length of \(\mathbf{y}\).

Let \(Z \geq (4Q'\lambda_1/\lambda_2)^{Q'}\). Note that \(Z\) is a constant depending only on the model and \(\Delta\). Let \(z_1/z, \ldots, z_{Q'}/z\) be the optimal simultaneous Diophantine approximation of \(x_1^*, \ldots, x_{Q'}^*\) with \(z_1, \ldots, z_{Q'}, z \in \mathbb{Z}\) and \(1 \leq z \leq Z\). By Dirichlet’s theorem we have

\[|zx_i^* - z_i| \leq Z^{-1/Q'} < 1. \tag{161}\]

Note that (161) implies

\[\text{if } x_i^* = 0 \text{ then } z_i = 0. \tag{162}\]

Also note that

\[\left| \sum_{i=1}^{Q'} zx_i^* - \sum_{i=1}^{Q'} z_i \right| \leq \sum_{i=1}^{Q'} |zx_i^* - z_i| \leq Q'Z^{-1/Q'} < 1,\]

and since \(z\) and \(z_i\)’s are integers and \((\mathbf{x}^*)^\top \mathbf{1} = 1\) we have

\[\sum_{i=1}^{Q'} \frac{z_i}{z} = 1. \tag{163}\]
From (162) and (163) we have that for $y := (z_1/z, \ldots, z_{Q'/z}) - x^*$ we can apply (159) and hence

$$(z_1/z, \ldots, z_{Q'/z})A(z_1/z, \ldots, z_{Q'/z})^T \geq O^* - \lambda_1 Q' Z^{-2/Q'} z^{-2}.$$  \hspace{1cm} (164)

Now we are ready to construct the gadget $J_1$. First, let $K$ be the multigraph on $z$ vertices $b_1, b_2, \ldots, b_z$ with the following symmetric edges: self-loop on $b_i$ for $i \in [z]$ and two edges between $b_i$ and $b_j$ for every $i, j \in [z]$ with $i \neq j$. To obtain $J_1$, we overlay two copies of $K$ as follows. Let $K_u$ (resp. $K_v$) be a copy of $K$, where the image of $b_z$ is renamed to $u$ (resp. $v$). Overlay $K_u, K_v$ by identifying the images of $b_1, \ldots, b_{z-1}$ in the two copies. Thus, the resulting graph $J_1$ has $z + 1$ vertices and the following edges: two self loops on $b_i$ for $i \in [z - 1]$, four edges between $b_i$ and $b_j$ for every $i, j \in [Q' - 1]$ with $i \neq j$, two edges between $u$ and $b_i$ for $i \in [z - 1]$, two edges between $v$ and $b_i$ for $i \in [z - 1]$ and a self loop on $u, v$.

Note that the weight of a phase assignment on $J_1$ is the sum of the induced phase assignments on $K_u$ and $K_v$. Consider an assignment of phases $\gamma_o$ such that in each complete graph $z_i$ vertices get phase $i$ (note that this forces the phases of $u$ and $v$ to be the same). The weight of the phase assignment $\gamma_o$ is

\[ \text{Lwt}_{J_1}(\gamma_o) = S_1 := 2(z_1, \ldots, z_{Q'})A(z_1, \ldots, z_{Q'})^T \geq 2z^2 O^* - 2\lambda_1 Q' Z^{-2/Q'}. \] \hspace{1cm} (165)\]

Now suppose that we have a phase assignment $\gamma$ for $J_1$ where the phases of $u$ and $v$ are different. Let $\hat{u}$ be the vector with $\hat{u}_i$ counting the number of vertices with phase $i$ in $K_u$ and define similarly $\hat{v}$.

Note that $\|\hat{u} - \hat{v}\|_2^2 = 2$ (since $\hat{u}$ and $\hat{v}$ differ in two coordinates—the phases of $u$ and $v$ in the assignment). By triangle inequality we have $\|\hat{u}/z - x^*\|_2 \geq 1/(z\sqrt{2})$ or $\|\hat{v}/z - x^*\|_2 \geq 1/(z\sqrt{2})$ (otherwise we would have $\|\hat{u}/z - \hat{v}/z\|_2 < \sqrt{2}/z$). W.l.o.g. assume that $\hat{u}/z$ has the greater distance from $x^*$. We have

\[ \text{Lwt}_{J_1}(\gamma_o) = S_2 := \hat{u}^T A\hat{u} + \hat{v}^T A\hat{v} \leq z^2 (2O^* - \lambda_2/(2z^2)) = 2z^2 O^* - \lambda_2/2. \] \hspace{1cm} (166)\]

By our choice of $Z$ we have $S_1 > S_2$ and hence in an optimal phase assignment for $J_1$ we have that $u$ and $v$ get the same phase. Note that we did not show which phase assignment
is optimal; we only found a phase assignment in which $u, v$ have the same phase that is better than any assignment in which $u, v$ have different phases.
CHAPTER VI

PHASE DIAGRAMS

In this chapter, we study the phase diagrams for spin systems of particular interest. We will be working on random $\Delta$-regular bipartite graphs, and hence phase diagrams should be understood as the maximizers $(\alpha, \beta)$ of the limit $\frac{1}{n} \log E_G[Z_G^{\alpha, \beta}]$, see also Definition 5 in Section 3.3. We do this for the following spin systems: antiferromagnetic 2-spin systems with external field, the ferromagnetic Potts model, the antiferromagnetic Potts and the colorings model.

Our general approach will be to use Theorem 2 as far as possible, that is, we will identify whenever possible the local maxima of the function $\Psi_1$. By Theorem 2, this is equivalent to identifying the stable fixpoints of the tree recursions. Of course, this is trivial when the parameters of the model lie in the uniqueness regime since there only one fixpoint exists, which by Theorem 5 corresponds to the (unique) global maximum of $\Psi_1$. Thus, the more interesting case is the non-uniqueness regime.

For antiferromagnetic 2-spin systems, identifying the stable fixpoints of the tree recursions will be sufficient to find the phases since they will be the only local maximizers of the function $\Psi_1$. In contrast, for the $q$-spin systems we investigate, more work is needed, essentially because the number of non-permutation symmetric fixpoints is a function of $q$.

For the ferromagnetic Potts model, the situation remains relatively simple: the non-permutation symmetric stable fixpoints turn out to not vary with $q$ and $\Delta$, and hence we can find the dominant phases by comparing the value of $\Psi_1$ at the local maximizers. An interesting phenomenon arises here, the so called phase coexistence. In particular, at a certain temperature $B = B_o$ (where $B_o$ is a function of $q, \Delta$), the global maximizers are no longer permutation symmetric and each has total measure a constant fraction of the Gibbs distribution. The phase coexistence phenomenon for the ferromagnetic Potts model has been observed and rigorously proved on the complete graph (this setting should be
considered simpler than ours) and on the grid $\mathbb{Z}^2$ (this setting should be considered harder than ours).

The analysis of dominant phases becomes much more complicated for the antiferromagnetic Potts model and the colorings model. First, the local maximizers now turn out to depend on both $q, \Delta$. Second, the structure of the local maximizers needs several variables to be captured, which makes analytical penetration much more intricate.

6.1 Antiferromagnetic 2-Spin Systems

A 2-spin system is specified by parameters $B_1, B_2 \geq 0$ and $\lambda > 0$. To avoid trivial models we will assume that at least one of $B_1, B_2$ is bigger than 0. The edge interaction matrix for a 2-spin system with parameters $B_1, B_2$ is given by

$$B = \begin{bmatrix} B_1 & 1 \\ 1 & B_2 \end{bmatrix}.$$ 

The system is antiferromagnetic if $B_1 B_2 < 1$ and ferromagnetic otherwise.

For a graph $G = (V, E)$ and a configuration $\sigma : V \rightarrow 0$, the weight of the configuration $\sigma$ is given by

$$w_G(\sigma) = \lambda^{\sigma^{-1}(0)} \prod_{(u,v) \in E} B_{\sigma(u), \sigma(v)},$$

and the partition function is given by $Z_G = \sum_{\sigma} w_G(\sigma)$.

We note that for $\Delta$-regular graphs, the external field $\lambda$ may be pushed into the interaction matrix $B$, giving a 2-spin system specified by the interaction matrix

$$B_\lambda = \begin{bmatrix} \lambda^{2/\Delta} B_1 & \lambda^{1/\Delta} \\ \lambda^{1/\Delta} & B_2 \end{bmatrix}.$$ 

Thus, Theorem 14 applies, provided that its assumptions are satisfied. As a first step, it is important to characterize the semi-transation invariant non-uniqueness regime for $B_\lambda$. For two-spin systems, this turns out to coincide with the non-uniqueness regime. As a starting point, we study the fixpoints of the tree recursions 8 for $B_\lambda$, which can be written as

$$R_0 \propto (B_1 C_0 + \lambda^{1/\Delta} C_1)^{\Delta-1} \text{ and } R_1 \propto (\lambda^{1/\Delta} C_0 + \lambda^{2/\Delta} B_2 C_1)^{\Delta-1},$$

$$C_0 \propto (B_1 R_0 + \lambda^{1/\Delta} R_1)^{\Delta-1} \text{ and } C_1 \propto (\lambda^{1/\Delta} R_0 + \lambda^{2/\Delta} B_2 R_1)^{\Delta-1}.$$  

(167)
We can easily transform the system (167) into a system with two variables, by substituting
\[ x' = \frac{R_0}{R_1} \text{ and } y' = \frac{C_0}{C_1}. \]
This gives the equivalent system of equations
\[ x' = \left( \frac{\lambda^2/\Delta B_1 y' + \lambda^{1/\Delta}}{\lambda^{1/\Delta} y' + B_2} \right)^{\Delta-1} \text{ and } y' = \left( \frac{\lambda^{2/\Delta} B_1 x' + \lambda^{1/\Delta}}{\lambda^{1/\Delta} x' + B_2} \right)^{\Delta-1}. \]
(168)

A further simplification is also possible giving a direct correspondence with the standard
form of the tree recursions for the original spin system (with the external field \( \lambda \)). Namely,
if we set \( x = \lambda^{1/\Delta} x' \) and \( y = \lambda^{1/\Delta} y' \), we obtain
\[ x = \lambda \left( \frac{B_1 y + 1}{y + B_2} \right)^{\Delta-1} \text{ and } y = \lambda \left( \frac{B_1 y + 1}{y + B_2} \right)^{\Delta-1}. \]
(169)
The system (169) always has a positive solution with \( x = y =: q \). The quantity \( q^* \) captures
the uniqueness regime. Precisely, the 2-spin system with parameters \( B_1, B_2, \lambda \) is in the
uniqueness regime of \( \hat{T}_\Delta \) iff
\[ (\Delta - 1)\omega \leq 1, \text{ where } \omega := \frac{(1 - B_1 B_2)q}{(B_2 + q)(1 + B_1 q)}. \]
(170)

To gain some intuition, let us look at the stability matrix of the tree recursions. By
Lemma 30, for a general interaction matrix \( B \), the condition for Jacobian stability of a
fixpoint of the tree recursions is related to the spectrum of \( L = \left[ \begin{array}{cc} 0 & A \\ \Lambda & 0 \end{array} \right] \), where \( A \) is the
\( q \times q \) matrix whose \( ij \)-entry is given by \( A_{ij} = B_{ij} R_i C_j / \sqrt{\alpha_i \beta_j} \) and \( \alpha_i, \beta_j \) are given by
(38). Recall that \( \pm 1 \) are eigenvalues of \( L \) and the condition for Jacobian stability is that all
the other eigenvalues have absolute value less than \( 1/(\Delta - 1) \) (see for details the proof of
Theorem 2 in Section 3.4.3). We next show that \( \pm \omega \) in (170) are the nontrivial eigenvalues
of \( L \) and hence, when \( (\Delta - 1)\omega < 1 \) the fixpoint \( x = y = q \) is Jacobian stable.

To do this, we trace back a solution to (167), which is given by \( R_0 \propto q/\lambda^{1/\Delta}, R_1 \propto 1 \)
and \( C_0 \propto q/\lambda^{1/\Delta}, C_1 \propto 1 \). The matrix \( A \) for the spin model \( B_\lambda \) is thus given by
\[
\begin{bmatrix}
\frac{B_1 q}{B_1 q + 1} & \frac{q^{1/2}}{(B_1 q + 1)^{1/2}(q + B_2)^{1/2}} \\
\frac{B_1 q^{1/2}}{(B_1 q + 1)^{1/2}(q + B_2)^{1/2}} & \frac{B_2}{q + B_2}
\end{bmatrix},
\]
whose eigenvalues are easily checked to be \( 1, -\omega \). Thus, the eigenvalues of \( J \) are \( \pm 1, \pm \omega \), as claimed.

The above arguments show that the translation invariant fixpoint of (167) is unstable in
the non-uniqueness regime of \( \hat{T}_\Delta \). By Theorem 2, it does not correspond to a Hessian local
maximum of $\Psi_1(\alpha, \beta)$. Thus, in the non-uniqueness regime of $T_\Delta$, the dominant phases correspond to positive solutions of (169) with $x \neq y$. It is a standard fact that there are exactly two such pairs $(q^+, q^-), (q^-, q^+)$. Both of these should correspond to the global maxima of $\Psi_1(\alpha, \beta)$. All we are left to do now is verify that they are Hessian local maxima, or equivalently (by Theorem 2) that the respective fixpoint of (169) is Jacobian stable.

Similar arguments as above yield that Jacobian stability of the two fixpoints is captured by the following inequality. For convenience, let $x = q^+, y = q^-$. Then

$$(\Delta - 1)^2 \omega^* < 1$$

where

$$\omega^* = \frac{(1 - B_1 B_2)^2 xy}{(B_1 x + 1)(B_1 y + 1)(B_2 + x)(B_2 + y)}.$$  \hfill (171)

We prove the following technical lemma.

**Lemma 61.** Every positive solution of (169) with $x \neq y$ satisfies (171).

For the proof of Lemma 61, we will use the following intermediate lemma.

**Lemma 62.** For $\Delta \geq 3$, every positive solution of (169) with $x \neq y$ satisfies

$$B_1 xy + B_1 B_2 (x + y) + B_2 \geq (\Delta - 2)(1 - B_1 B_2) \sqrt{xy}.$$  

With Lemma 62, it is easy to establish Lemma 171.

**Proof of Lemma 61.** Let $W := B_1 xy + B_1 B_2 (x + y) + B_2$. Observe that

$$W = (B_1 x + 1)(y + B_2) - (1 - B_1 B_2)y = (B_1 y + 1)(x + B_2) - (1 - B_1 B_2)x.$$  

Using the two expressions of $W$ and the AM-GM inequality, we obtain

$$W^2 = (B_1 x + 1)(y + B_2)(B_1 y + 1)(x + B_2) + (1 - B_1 B_2)^2 xy$$

$$- (1 - B_1 B_2)(y(B_1 x + 1)(B_2 + y) + x(B_1 y + 1)(B_2 + x))$$

$$\leq (\sqrt{(B_1 x + 1)(B_1 y + 1)(B_2 + y)}(B_2 + y) - (1 - B_1 B_2)\sqrt{xy})^2.$$  \hfill (172)

Equality in (172) can only hold if $y(B_1 x + 1)(B_2 + y) = x(B_1 y + 1)(B_2 + x)$, which in conjunction with (169) gives $x = y$. Thus, the inequality (172) is in fact strict. To take square roots in (172), note that trivially

$$(B_1 x + 1)(B_1 y + 1)(B_2 + x)(B_2 + y) > xy > (1 - B_1 B_2)^2 xy.$$
so (172) and Lemma 62 give
\[
\sqrt{(B_1x + 1)(y + B_2)(B_1y + 1)(x + B_2)} - (1 - B_1 B_2)\sqrt{xy} > (\Delta - 2)(1 - B_1B_2).
\]
which after massaging gives (171).
\[\square\]

**Proof of Lemma 62.** For convenience, set \(d = \Delta - 1\). The \(x, y\) satisfy
\[
x = \lambda \left(\frac{B_1 y + 1}{y + B_2}\right)^d \quad \text{and} \quad y = \lambda \left(\frac{B_1 x + 1}{x + B_2}\right)^d.
\]
It follows that
\[
x \left(\frac{B_1 x + 1}{x + B_2}\right)^d = y \left(\frac{B_1 y + 1}{y + B_2}\right)^d \Rightarrow x \left((B_1 x + 1)(y + B_2)\right)^d = y \left((B_1 y + 1)(x + B_2)\right)^d. \quad (173)
\]
Let \(W := B_1 xy + B_1 B_2 x + B_1 B_2 y + B_2\). Observe that
\[
(B_1 x + 1)(y + B_2) = B_1 xy + B_1 B_2 x + y + B_2 = W + (1 - B_1 B_2)y,
\]
\[
(B_1 y + 1)(x + B_2) = B_1 xy + B_1 B_2 y + x + B_2 = W + (1 - B_1 B_2)x.
\]
Hence, (173) gives
\[
x (W + (1 - B_1 B_2)y)^d = y (W + (1 - B_1 B_2)x)^d.
\]
Expanding using Newton’s formula gives
\[
x \sum_{k=0}^{d} \binom{d}{k} W^{d-k} ((1 - B_1 B_2)y)^k = y \sum_{k=0}^{d} \binom{d}{k} W^{d-k} ((1 - B_1 B_2)x)^k,
\]
which is equivalent to
\[
W^d (x - y) = xy \sum_{k=2}^{d} \binom{d}{k} W^{d-k} (1 - B_1 B_2)^k \left(x^{k-1} - y^{k-1}\right).
\]
Since \(x \neq y\), this can be rewritten as
\[
W^d = xy \sum_{k=2}^{d} \binom{d}{k} W^{d-k} (1 - B_1 B_2)^k \left(\frac{x^{k-1} - y^{k-1}}{x - y}\right). \quad (174)
\]

**Claim 63.** For \(k \geq 2\) and \(x, y > 0\) with \(x \neq y\), it holds that \(\frac{x^{k-1} - y^{k-1}}{x - y} \geq (k - 1)(xy)^{(k-2)/2}\).
The simple proof of Claim 63 is given at the end. Using Claim 63, (174) gives

\[ W^d \geq \sum_{k=2}^{d} \binom{d}{k} (k-1) W^{d-k}(1 - B_1 B_2)^k (xy)^{k/2}, \]

or equivalently

\[ W^d + \sum_{k=2}^{d} \binom{d}{k} W^{d-k}(1 - B_1 B_2)^k (xy)^{k/2} \geq \sum_{k=2}^{d} \binom{d}{k} k W^{d-k}(1 - B_1 B_2)^k (xy)^{k/2}. \]  \hspace{1cm} (175)

Using again Newton's formula and the identity \( \binom{d}{k} = d \binom{d-1}{k-1} \), we have

\[
C = (W + (1 - B_1 B_2)\sqrt{xy})^d - dW^{d-1}(1 - B_1 B_2)\sqrt{xy}, \\
D = d(1 - B_1 B_2)\sqrt{xy} \sum_{k=2}^{d} \binom{d-1}{k-1} W^{d-k}(1 - B_1 B_2)^{k-1} (\sqrt{xy})^{k-1} \\
= d(1 - B_1 B_2)\sqrt{xy} \left((W + (1 - B_1 B_2)\sqrt{xy})^{d-1} - W^{d-1}\right). 
\]

Thus, (175) gives

\[ W \geq (d-1)(1 - B_1 B_2)\sqrt{xy}, \]

which is exactly the inequality we wanted. Finally, we give the proof of Claim 63.

**Proof of Claim 63.** Since \( k \geq 2 \), observe that

\[ \frac{x^{k-1} - y^{k-1}}{x - y} = x^{k-2} + x^{k-3}y + \ldots + y^{k-2} \geq (k-1) \left((xy)^{(k-1)(k-2)/2}\right)^{1/(k-1)} = (k-1)(xy)^{(k-2)/2}. \]

The inequality is an application of the AM-GM inequality to \( x^{k-2}, \ldots, y^{k-2} \). Equality holds iff \( x = y \). \hfill \Box

This completes the proof of Lemma 62. \hfill \Box

### 6.2 Ferromagnetic Potts model

Häggström [22] established that the uniqueness threshold \( \mathfrak{B}_u \) for the \( q \)-state ferromagnetic Potts model with parameter \( B \) is the unique value for which the following polynomial has a double root in \( (0, 1) \):

\[ (q - 1)x^{\Delta} + (2 - B - q)x^{\Delta-1} + Bx - 1. \]  \hspace{1cm} (176)
We prove that the ferromagnetic Potts model on random Δ-regular graphs undergoes a first order phase transition at a parameter $\mathcal{B}_o > \mathcal{B}_u$, (which was considered by Peruggi et al. [45]):

$$\mathcal{B}_o := \frac{q - 2}{(q - 1)(1 - 2/\Delta) - 1}.$$  

Finally, Häggström [22] considers the following activity $\mathcal{B}_{rc}$, which he conjectures is a (second) threshold for uniqueness of the random-cluster model, defined as:

$$\mathcal{B}_{rc} := 1 + \frac{q}{\Delta - 2}.$$  

Note, $\mathcal{B}_u < \mathcal{B}_o < \mathcal{B}_{rc}$.

In this section we prove the following Theorem 64 detailing the phase diagram for the Potts model. This consists of $q + 1$ phases; the disordered phase and $q$ permutation symmetric ordered phases. The disordered phase corresponds the uniform fixpoint with $\alpha = (1/q, \ldots, 1/q)$. When we refer to an ordered phase $\alpha$ this refers specifically to a phase with one color dominating in the following sense: one coordinate is equal to $a > 1/q$ and the other $q - 1$ coordinates are equal to $(1 - a)/(q - 1)$.

**Theorem 64.** For the ferromagnetic Potts model the following holds at activity $B$:

- $B < \mathcal{B}_u$: There is a unique infinite-volume Gibbs measure on $\mathbb{T}_\Delta$. The disordered phase is Hessian dominant phase, and there are no other local maxima of $\Psi_1$.

- $\mathcal{B}_u < B < \mathcal{B}_{rc}$: The local maxima of $\Psi_1$ are the disordered phase $\mathbf{u}$ and the $q$ ordered phases (the ordered phases are permutations of each other). All of these $q + 1$ phases are Hessian local maxima. Moreover:
  - $\mathcal{B}_u < B < \mathcal{B}_o$: The disordered phase is Hessian dominant.
  - $B = \mathcal{B}_o$: Both the disordered phase and the ordered phases are Hessian dominant.
  - $\mathcal{B}_o < B < \mathcal{B}_{rc}$: The ordered phases are Hessian dominant.

- $B \geq \mathcal{B}_{rc}$: The $q$ ordered phases (which are permutations of each other) are Hessian dominant. For $B > \mathcal{B}_{rc}$ there are no other local maxima of $\Psi_1$.  

133
To prove Theorem 64, in light of Theorem 2, in order to determine the local maxima for the Potts model, we need to compute the spectral radius of the map $L : (r_1, \ldots, r_q) \mapsto (\hat{r}_1, \ldots, \hat{r}_q)$, given by

$$\hat{r}_i = \sum_{j=1}^{q} \frac{B_{ij} R_i R_j}{\sqrt{\alpha_i \alpha_j}} r_j$$  \hspace{1cm} (177)

in the subspace

$$\sum_{i=1}^{q} \sqrt{\alpha_i} r_i = 0,$$  \hspace{1cm} (178)

where the $R_i$’s are fixed points of the tree recursions and the $\alpha_i$’s are given by

$$\alpha_i = R_i \sum_{j=1}^{q} B_{ij} R_j \text{ for } i = 1, \ldots, q.$$

Our goal is to determine the local maxima by verifying when the spectral radius of this map (in the subspace) is less than $1/(\Delta - 1)$.

First we argue that the solutions of the tree recurrences for the Potts model are simple—they have only two values.

**Lemma 65.** Let $(R_1, \ldots, R_q)$ be a solution of the tree recursion of ferromagnetic Potts model. Then the $R_i$’s have at most two distinct values.

**Proof.** Let $r_i = R_i^{1/d}$ and $r = \sum_{i=1}^{q} r_i^d$, where $d := \Delta - 1$. We have

$$r_i = r + (B - 1) r_i^d.$$

The polynomial $f(x) = (B - 1)x^d - x + r$ has at most 2 positive roots (counted with their multiplicities; by the Descartes’ rule of signs) and hence there are at most 2 different values of the $r_i$’s. \hfill \Box

Let

$$M = \left\{ \frac{B_{ij} R_i R_j}{\sqrt{\alpha_i \alpha_j}} \right\}_{i,j=1}^{q},$$

be the matrix of the linear map $L$. Note that $M$ is symmetric and has an eigenvalue equal to 1 with eigenvector $e = [\sqrt{\alpha_1}, \ldots, \sqrt{\alpha_q}]^T$.

**Lemma 66.** The fixed points of the tree recursions, assuming $R_1 \geq R_2 \geq \ldots R_q$, satisfy $R_1 = R_2 = \ldots = R_t$ and $R_{t+1} = \ldots = R_q$ for some $1 \leq t \leq q$. It follows that $\alpha_1 = \alpha_2 = \ldots = \alpha_t$ and $\alpha_{t+1} = \ldots \alpha_q$. 

134
Proof. This follows from Lemma 65.

Remark 10. Two settings for $t$ in the setting of Lemma 66 will be of particular interest, namely $t = 1$ and $t = q$. We shall refer to the latter as the uniform fixpoint, and this corresponds to the disordered phase. We shall refer to fixpoints with $t = 1$ as the “majority” fixpoints. This class includes either one or two (depending on the value of $B$, c.f. Lemma 70) fixpoints where color 1 dominates and the remaining appear with equal probability. The ordered phases correspond to the majority fixpoint for which the ratio $R_1/R_q$ is maximum.

Lemma 66 implies that $M$ has a very simple structure. The following simple lemma describes the eigenvalues of $M$.

Lemma 67. Assume $1 \leq t < q$. Then $M$ has the following eigenvalues:

- $1$ with multiplicity 1,
- $\frac{(B - 1)R_1^2}{\alpha_1}$ with multiplicity $t - 1$ (assuming $t > 1$),
- $\frac{(B - 1)R_q^2}{\alpha_q}$ with multiplicity $q - t - 1$ (assuming $t < q - 1$), and
- $\frac{(B + t - 1)R_1^2}{\alpha_1} + \frac{(B + q - t - 1)R_q^2}{\alpha_q} - 1$ with multiplicity 1.

For $t = q$ the eigenvalues of $M$ are

- $1$ with multiplicity 1,
- $\frac{(B - 1)R_1^2}{\alpha_1}$ with multiplicity $q - 1$.

Proof. We already described the eigenvector for 1. A vector with 1 at position 1 and $-1$ at a position $i$ for $2 \leq i \leq t$ (and zeros elsewhere) yields eigenvalue $(B - 1) \frac{R_1^2}{\alpha_1}$. Similarly, a vector with 1 at position $q$ and $-1$ at a position $i$ for $t + 1 \leq i < q$ (and zeros elsewhere) yields eigenvalue $(B - 1) \frac{R_q^2}{\alpha_q}$. Note that in the case $t = q$ this accounts for all the eigenvalues. In the case $t < q$ we deduce the remaining eigenvalue by considering the trace of $M$:

$$
\frac{tBR_1^2}{\alpha_1} + (q - t)t \frac{BR_q^2}{\alpha_q} - (t - 1) \frac{(B - 1)R_1^2}{\alpha_1} - (q - t - 1) \frac{(B - 1)R_q^2}{\alpha_q} - 1.
$$

$\square$
Lemma 68. The uniform fixed point is stable if \((\Delta - 2)(B - 1) < q\). The uniform fixed point is unstable if \((\Delta - 2)(B - 1) > q\).

Proof. The solution of the tree recurrences considered is \(R_1 = \cdots = R_q\) and hence \(\alpha_1 = \cdots = \alpha_q = (B + q - 1)R_1^2\). The only relevant eigenvalue is \((B - 1)/(B + q - 1)\) (with multiplicity \(q - 1\)), which we compare with \(1/(\Delta - 1)\) to obtain the result.

Lemma 68 allows us to restrict our focus on \(q - 1 \geq t \geq 1\). In this setting, the tree equations give, with \(x := y^d := \frac{R_1}{R_q}\) and \(d = \Delta - 1\),

\[
x = \left(\frac{(B + t - 1)x + (q - t)}{tx + (B + q - t - 1)}\right)^d \text{ or } B - 1 = \frac{(y - 1)\left(tx^d + q - t\right)}{y^d - y}.
\]

The following lemma implies that all fixed points with \(q - 1 \geq t \geq 2\) are unstable in the whole non-uniqueness regime, since the respective matrices have an eigenvalue greater than \(1/(\Delta - 1)\).

Lemma 69. When \(\frac{R_1}{R_q} > 1\), it holds that \((B - 1)\frac{R_q^2}{\alpha_1} > \frac{1}{\Delta - 1}\).

Proof. The desired inequality is equivalent to

\[(\Delta - 1)(B - 1)R_1 > (B + t - 1)R_1 + (q - t)R_q,
\]

which after simple manipulations reduces into

\[((\Delta - 2)(B - 1) - t)\frac{R_1}{R_q} > q - t.
\]

Substituting \(\frac{R_1}{R_q} = y^d\) and \(B - 1\) from equation (179), the inequality becomes

\[
\left(\frac{(d - 1)(y - 1)\left(ty^d + q - t\right)}{y^d - y} - t\right) y^d - (q - t) > 0.
\]

Doing the necessary simplifications, we obtain the following equivalent inequality

\[
\frac{((d - 1)y^{1+d} - dy^d + y)\left(q + t\left(y^d - 1\right)\right)}{y^d - y} > 0.
\]

Since \(y > 1\), the only non-trivial factor to prove positivity is \(p(y) := (d - 1)y^{d+1} - dy^d + y\). By Descartes’ rule of signs, \(p\) can have at most two positive roots. It holds that \(p(1) = p'(1) = 0\), so that \(p(y)\) is always positive for \(y > 1\).
In light of Lemma 69, we need to classify fixpoints with \( t = 1 \), the majority fixpoints. The following lemma gives the number of such majority fixpoints in the regimes of interest.

**Lemma 70.** When \( \mathcal{B}_u \leq B < \mathcal{B}_{rc} \), there are exactly two majority fixpoints. When \( B \geq \mathcal{B}_{rc} \), there is exactly one majority fixpoint.

**Proof.** We need to look at (179) for \( t = 1 \) and check how many values of \( y > 1 \) satisfy the equation in the two different regimes. For \( t = 1 \), the equation reads as

\[
B - 1 = f(y) := \frac{(y - 1)(y^d + q - 1)}{y^d - y}, \quad \text{so that} \quad f'(y) = \frac{p(y)}{(y^d - y)^2},
\]

where \( p(y) \) is the polynomial

\[
p(y) := y^{2d} - dy^{d+1} - (d - 1)(q - 2)y^d + d(q - 1)y^{d-1} - (q - 1).
\]

Employing the Descartes’ rule of signs we see that \( p \) has one or three positive roots counted by multiplicities. It is easy to check that \( p(1) = p'(1) = 0 \), so that \( p \) has in fact 3 positive roots (since 1 is a double root), let \( \rho \) denote the other positive root. We next prove that \( \rho > 1 \) so that \( p(y) \geq 0 \) if \( 1 \leq y \leq \rho \) and \( p(y) \geq 0 \) if \( y \geq \rho \). It follows that for positive \( y \) we have \( p(y) > 0 \) iff \( y > \rho \).

To prove that \( \rho > 1 \), for the sake of contradiction assume that \( 0 < \rho \leq 1 \). If \( \rho = 1 \), then 1 is a root with multiplicity 3 of the polynomial \( p(y) \) and hence \( p''(1) = 0 \). By straightforward calculations we see that \( p''(1) = (q - 2)(d - d^2) \) which is clearly non-zero for \( q \geq 3 \) and \( d \geq 3 \). Thus, we may assume that \( 0 < \rho < 1 \). Since \( p(1) = p(\rho) = 0 \), by Rolle’s theorem there is a root \( \rho' \in (\rho, 1) \) of the polynomial \( p'(y) = dy^{d-2}g(y) \) where

\[
g(y) := 2y^{d+1} - (d + 1)y^2 - (d - 1)(q - 2)y + (d - 1)(q - 1).
\]

Since \( g(1) = g(\rho') = 0 \), by the same token there is a root \( \rho'' \in (\rho', 1) \) of

\[
g'(y) = 2(d + 1)y^d - 2(d + 1)y - (d - 1)(q - 2).
\]

We thus obtain the desired contradiction since, for \( q \geq 3 \) and \( d \geq 2 \), \( g'(y) < 0 \) for all \( y \in [0, 1] \).
Now observe that \( f(y) \to \infty \) as \( y \to \infty \), while \( f(y) \to \frac{q}{d-1} \) as \( y \to 1^+ \). Thus, when \( y \to 1^+ \), \( B \), as given by (180), goes to \( \mathfrak{B}_m \) from below.

To obtain the lemma, it thus suffices to show that at \( y = \rho \), we have \( B = \mathfrak{B}_u \). Recall, that \( \mathfrak{B}_u \) is the unique value of \( B \) for which the polynomial \( (q-1)z^{d+1} + (2-B-q)z^d + Bz - 1 \) has a double root in \((0, 1)\). We reparameterize \( z \to 1/z \), so that \( \mathfrak{B}_u \) is the unique value of \( B \) for which the following polynomial has a double root in \((1, \infty)\):

\[
r(z) = z^{d+1} - Bz^d - (2 - B - q)z - (q - 1).
\]

Let \( z_c \) be the double root of this polynomial when \( B = \mathfrak{B}_u \). Solving each of \( r(z_c) = 0 \) and \( r'(z_c) = 0 \) with respect to \( B \) and equating the expressions, we obtain that \( p(z_c) = 0 \). It follows that \( \rho = z_c \), as wanted.

We can now classify the stability of fixpoints with \( t = 1 \).

**Lemma 71.** Exactly one majority fixed point is stable. More precisely, the only stable fixed point with \( t = 1 \) is the one maximizing the ratio \( x \).

**Proof.** In the setting of Lemma 66 we have \( t = 1 \) and thus the interesting eigenvalues of \( M \) are \( R_2^d/\alpha_q \) and \( BR^2_1/\alpha_q + (B + q - 2)R^2_q/\alpha_q - 1 \). One can easily check that the former is always larger, so it suffices to check when the following inequality holds

\[
Q := BR^2_1/\alpha_q + (B + q - 2)R^2_q/\alpha_q - \frac{\Delta}{\Delta - 1} < 0. \tag{182}
\]

Expanding everything out, we have

\[
Q = \frac{BR_1}{BR_1 + (q - 1)R_q} + \frac{(B + q - 2)R_q}{R_1 + (q - 2 + B)R_q} - \frac{\Delta}{\Delta - 1}
= \frac{R_1R_q((\Delta - 2)B(q - 2 + B) - \Delta(q - 1)) - BR^2_1 - (q - 1)(q - 2 + B)R^2_q}{(\Delta - 1)(BR_1 + (q - 1)R_q)(R_1 + (q - 2 + B)R_q)}.
\]

Thus it suffices to check, with \( x = \frac{R_1}{R_q} \), when

\[
((\Delta - 2)B(q - 2 + B) - \Delta(q - 1))x < Bx^2 + (q - 1)(q - 2 + B). \tag{183}
\]

Substituting \( x = y^d \) and \( B - 1 \) from (179), we obtain the equivalent inequality

\[
0 < \frac{y(y^d - 1)(y^d + q - 1) p(y)}{(y^d - y)^2}.
\]
where \( p(y) \) is the polynomial given in (181). By the proof of Lemma 70, \( p(y) > 0 \) iff \( y > \rho \). The latter inequality, throughout the regime \( B \geq B_u \), is only satisfied by the majority fixpoint with \( x \) maximum, concluding the proof.

Having classified the fixpoints which are Jacobian attractive, we now need to see when these are dominant. This entails comparing the values of \( \Psi_1 \) for the respective phases. Rather than doing this directly, we use Lemma 5. In particular, it is equivalent to compare the values of \( \Phi_1 \) at the fixpoints. Moreover, note that the expression (238) is invariant upon scaling \( R_i \)’s by the same factor and hence we only need to compare \( \Phi_1(x,1,\ldots,1) \) and \( \Phi_1(1,\ldots,1) \), where \( x \) is a solution of (179) for \( t = 1 \).

**Lemma 72.** Let \( t = 1 \) and \( x \) be the solution of (179) with \( x \) maximum. Then \( \Phi_1(x,1,\ldots,1) \geq \Phi_1(1,1,\ldots,1) \) iff \( B \geq B_o \). Equality holds iff \( B = B_o \).

**Proof.** By a direct calculation

\[
\Phi_1(x,1,\ldots,1) = \frac{\Delta}{2} \log \left( (x + q - 1)^2 + (B - 1)(x^2 + q - 1) \right) - (\Delta - 1) \log \left( x^{\Delta/(\Delta - 1)} + q - 1 \right),
\]

\[
\Phi_1(1,1,\ldots,1) = \frac{\Delta}{2} \log \left( q^2 + (B - 1)q \right) - (\Delta - 1) \log \left( q \right).
\]

Using the substitutions \( d = \Delta - 1, x = y^d \) and the second equation in (179), after careful manipulations we obtain

\[
DIF := \Phi_1(x,1,\ldots,1) - \Phi_1(1,1,\ldots,1) = \log \left( \frac{(y^d + q - 1)^{d+1}}{(y^{d+1} + q - 1)^{d-1}} \right) \frac{y + q - 1}{q^{d-1}}.
\]

It is straightforward to check that for \( y = (q - 1)^{2/(d+1)} \), \( DIF = 0 \). The respective value of \( B \) for this value of \( y \) is given by the second equation in (179) and equals \( B_o \). Thus, it suffices to show that \( y \) is an increasing function of \( B \) and \( DIF \) increases as \( y \) increases. This is indeed true. By (179), one calculates

\[
\frac{\partial y}{\partial B} \cdot \frac{p(y)}{y(y^d - y)^2} = 1,
\]

and

\[
\frac{\partial DIF}{\partial y} = \frac{(d + 1)(q - 1)p(y)}{y(y + q - 1)(y^d + q - 1)(y^{d+1} + q - 1)},
\]

where \( p(y) \) is the polynomial defined in Lemma 69, whose positivity has already been established. The claim follows.
Proof of Theorem 64. We first argue about the local maxima of the function $\Psi_1$. To use the results proved in this section, we apply Theorem 2: we just need to check the stability of the corresponding fixpoints. As proved in Lemma 69, only the disordered phase and the $q$ ordered phases can be local maxima. The disordered phase, by Lemma 68, is Jacobian stable when $1 < B \leq B_{rc}$. The $q$ ordered phases (which are permutations of each other), by Lemmas 69 and 71, are Jacobian stable when $B \geq B_u$.

To argue about the dominant phases, we need to find the regimes where the disordered/ordered phases are dominant. Lemma 72 says that the disordered phase is dominant iff $B \leq B_o$, whereas the $q$ ordered phases iff $B \geq B_o$. To finish the proof of Theorem 64, we only need to argue that the phases are also Hessian dominant in the respective regimes. This follows immediately by Theorem 2, since Jacobian stability is equivalent to a Hessian phase. Thus, since we classified local maxima of $\Psi_1$ using the Jacobian stability of the corresponding fixpoints, the statements about the Hessian phases follow from the preceding discussion.

6.3 Antiferromagnetic Potts model and Colorings

6.3.1 Proof Outline

To obtain Theorems 11 and 12, we verify the hypotheses of Theorem 14 for the global maxima of $\Psi_1$ for the antiferromagnetic Potts and colorings models. Recall, the interaction matrix $B$ for the Potts model is completely determined by a parameter $B$, which is equal to $\exp(-\beta)$ where $\beta$ is the inverse temperature in the standard notation for the Potts model. The antiferromagnetic regime corresponds to $0 < B < 1$. The coloring model is the zero temperature limit of the Potts model and corresponds to the particular case $B = 0$ in what follows. We should note that in Statistical Physics terms, the arguments of this section are closely related to the phase diagrams of the models.

The most crucial component is to obtain characterizations of the global maxima of $\Psi_1$. To be able to apply Theorem 14, our goal is to prove that the global maxima of $\Psi_1$ in the regime $0 \leq B < \frac{\Delta - q}{\Delta}$ are (i) not translation-invariant, (ii) Hessian maxima, and (iii) permutation symmetric, see Section 1.4.4 for the definitions of these terms. We will in fact
show the stronger statement that condition (i) is met only in the regime \(0 \leq B < \frac{\Delta - 2}{\Delta}\), which shows that the inapproximability results of Theorems 11 and 12 are best possible for any reduction which uses bipartite graphs as gadgets. We next outline our methods.

By Theorem 5 specified to the antiferromagnetic Potts and colorings models, studying the global maxima of \(\Psi_1\) is equivalent to studying the global maxima of \(\Phi\). Moreover, the global maxima of \(\Phi\) and \(\Psi_1\) occur at their critical points. Since there is a one-to-one correspondence between the critical points of \(\Phi\) and the critical points of \(\Psi_1\) (given by (11)), we will freely interchange our focus between critical points of \(\Phi\) and \(\Psi_1\).

The critical points of \(\Phi\), by the first part of Theorem 5, are given by fixpoints of the tree recursions, which for the Potts model are positive solutions to the following system of equations:

\[
R_i \propto (BC_i + \sum_{j \neq i} C_j)^d, \quad C_j \propto (BR_j + \sum_{i \neq j} R_i)^d, \tag{184}
\]

where \(i, j = 1, \ldots, q\) and \(d\) is the notational convenient substitution \(d := \Delta - 1 \geq 2\). Given a fixpoint of the tree recursions (184), we will classify whether it is a Hessian local maximum of \(\Psi_1\) using Theorem 2.

Once we find the global maxima of \(\Psi_1\), it will be simple to prove that they are Hessian and permutation symmetric. Finding however the global maxima of \(\Psi_1\) is going to be more intricate, mainly because the number of local maxima varies according to the value of \(B\).

We will thus have to compare the values of \(\Psi_1\) at the critical points. Rather than doing this directly (which seems as a difficult task), we solve a relaxed optimisation problem, which for \(q\) even can be tied to the maximization of \(\Psi_1\). We next give the details.

We begin our considerations by examining when a fixpoint (184) is translation invariant, i.e., satisfies \(R_i \propto C_i\) for every \(i \in [q]\).

**Lemma 73.** Let \(0 \leq B < 1\) and \(\Delta \geq 3\). Then a solution of (184) satisfies \(R_i \propto C_i\) for every \(i \in [q]\) iff \(R_1 = \ldots = R_q\) and \(C_1 = \ldots = C_q\).

**Proof of Lemma 73.** We first prove the forward direction. By the symmetries of the model, we may assume an arbitrary ordering of the \(R_i\)'s. Since \(0 \leq B < 1\), equations (184) easily imply the reverse ordering of the \(C_i\)'s. Thus, \(R_i \propto C_i\) for every \(i \in [q]\) implies that the
ordering must be trivial, i.e, \( R_1 = \ldots = R_q \) and \( C_1 = \ldots = C_q \). The backward direction is trivial.

**Corollary 74.** Translation invariant fixpoints (184) always exist and are unique up to scaling.

We next explore in which regimes of \( B \), the critical points of \( \Phi \) consist solely of translation invariant fixpoints. In this regime, we immediately obtain by Theorem 5 that the global maximum of \( \Psi_1 \) (and hence the global maximum of \( \Phi \) as well) is achieved at a translation invariant fixpoint.

**Lemma 75.** Let \( 0 \leq B < 1 \) and \( \Delta \geq 3 \). When \( q \geq \Delta \) and \( 0 \leq B < 1 \) or \( q < \Delta \) and \( \frac{\Delta - q}{\Delta} \leq B < 1 \), the system of equations (184) admits a positive solution iff

\[
R_1 = \ldots = R_q \text{ and } C_1 = \ldots = C_q.
\]

The proof of Lemma 75 is an extension of an argument in [7] for colorings and is given in Section 6.3.5.1. The next lemma states that in the complementary regime of Lemma 75, the translation invariant fixpoint does not correspond to a local maximum of \( \Psi_1 \) and hence, by Theorem 5, the global maximum of \( \Psi_1 \) occurs at a fixpoint of (184) which is not translation invariant. In particular, in this regime we have semi-translational non-uniqueness.

**Lemma 76.** For \( q < \Delta \) and \( 0 \leq B < \frac{\Delta - q}{\Delta} \), the global maximum of \( \Psi_1 \) is not achieved at the translation invariant fixpoint.

**Proof of Lemma 76.** We apply Theorem 2 by showing that the translation invariant fixpoint is Jacobian unstable and hence not a local maximum of \( \Psi_1 \). By Lemma 30, for a general interaction matrix \( B \), the condition for Jacobian stability of a fixpoint of the tree recursions is related to the spectrum of \( L = \begin{bmatrix} 0 & A \\ A^T & 0 \end{bmatrix} \), where \( A \) is the \( q \times q \) matrix whose \( ij \)-entry is given by \( A_{ij} = B_{ij}R_iC_j/\sqrt{\alpha_i\beta_j} \) and \( \alpha_i, \beta_j \) are given by (38). Recall that \( \pm 1 \) are eigenvalues of \( L \) and the condition for Jacobian stability is that all the other eigenvalues have absolute value less than \( 1/(\Delta - 1) \) (see for details the proof of Theorem 2 in Section 3.4.3).

In the setting of the lemma, the matrix \( A \) for the translation invariant fixpoint has off-diagonal entries equal to \( 1/(B + q - 1) \) and diagonal entries equal to \( B/(B + q - 1) \). It
follows that the eigenvalues of $L$ are $\pm 1$ by multiplicity 1 and $\pm (1 - B)/(B + q - 1)$ by multiplicity $q - 1$. The absolute value of the latter is greater than $\frac{1}{\Delta - 1}$ for $0 \leq B < \frac{\Delta - q}{\Delta}$, as claimed.

We summarize the above results into the following corollary.

**Corollary 77.** When $q \geq \Delta$ and $0 \leq B < 1$ or $q < \Delta$ and $\frac{\Delta - q}{\Delta} \leq B < 1$, $\Psi_1$ has a unique global maximum for $\alpha_1 = \ldots = \alpha_q = \beta_1 = \ldots = \beta_q = 1/q$ or, in other words, the global maximum of $\Psi_1$ is achieved by the (unique) translation invariant Gibbs measure. In the complementary regime $q < \Delta$ and $0 \leq B < \frac{\Delta - q}{\Delta}$, the maximum of $\Psi_1$ is not achieved at the translation invariant fixpoint, and hence it is achieved at a semi-translation invariant fixpoint which is not translation invariant.

Corollary 77 is not sufficient to obtain Theorems 11 and 12, since we need to verify that the global maxima of $\Psi_1$ in semi-translational non-uniqueness are Hessian and permutation symmetric. We do this by identifying the critical points which are maxima of $\Psi_1$.

To state the result, we first need the following structural statement for the solutions of equations (184), namely that solutions of (184) are supported on at most 3 values for the $R_i$’s and similarly for the $C_j$’s.

**Lemma 78.** Let $(R_1, \ldots, R_q, C_1, \ldots, C_q)$ be a positive solution of the system (184). Let $t_R$ be the number of values on which the $R_i$’s are supported and define similarly $t_C$. Then $t_R, t_C \leq 3$ and $t_R = t_C = t$.

The proof of Lemma 78 is given in Section 6.3.5. Lemma 78 motivates the following definition.

**Definition 11.** From Lemma 78, the $R_i$’s and $C_j$’s of a fixpoint of (184) attain at most $t \leq 3$ different values. Let $\tilde{R}_1, \ldots, \tilde{R}_t$ and $\tilde{C}_1, \ldots, \tilde{C}_t$ be their values and let $q_1, \ldots, q_t \geq 1$ be their multiplicities. When $t = 1$, define $q_2 = q_3 = 0$; when $t = 2$, define $q_3 = 0$; when $q_t = 0$, define the values of $\tilde{R}_i, \tilde{C}_i$ to be zero. The corresponding solution of (184) or equivalently the fixpoint of the tree recursions is then defined to be of type $(q_1, q_2, q_3)$. Note that $q_1 + q_2 + q_3 = q$ and the $q_i$’s are non-negative integers. Call a $(q_1, q_2, q_3)$-type fixpoint to be $t$-supported if the number of $q_i$’s which are non-zero equals $t$. 

143
Finding the types of fixpoints which correspond (via (11)) to global maxima of $\Psi_1$ is not a trivial task. While 2-supported fixpoints are simple to handle, this is not the case for 3-supported fixpoints. The main lemma we prove is the following, which identifies the type of fixpoints which maximize $\Psi_1$.

**Lemma 79.** For $0 \leq B < \frac{\Delta - q}{\Delta}$ and even $q \geq 3$, the maximum of $\Psi_1$ over $(q_1, q_2, q_3)$-type solutions of (184) is attained at fixpoints of type $(q/2, q/2, 0)$.

The final piece is to show that fixpoints of type $(q/2, q/2, 0)$ are Hessian maxima of $\Psi_1$ and permutation symmetric. This is the scope of the next lemma, whose proof is given in Section 6.3.5.

**Lemma 80.** For $0 \leq B < \frac{\Delta - q}{\Delta}$ and even $q \geq 3$, fixpoints of type $(q/2, q/2, 0)$ are Jacobian stable and hence correspond to Hessian maxima of $\Psi_1$. The values of $R_i$’s and $C_j$’s for fixpoints of type $(q/2, q/2, 0)$ are unique up to scaling and permutations of the colours.

With Lemmas 79 and 80 at hand, it is straightforward to obtain Theorems 11 and 12 by applying the inapproximability result of Theorem 14.

**Proof of Theorems 11 and 12.** By Theorem 14, it suffices to check that the maxima of $\Psi_1$ are permutation symmetric and Hessian local maxima. By Theorem 5, the maximum of $\Psi_1$ happens at a critical point, which correspond (via (11)) to fixpoints (184). By Lemma 79, the fixpoints (184) which correspond to maximizers of $\Psi_1$ are of type $(q/2, q/2, 0)$. Note that the scaling of $R_i$’s and $C_j$’s does not affect the values of $\alpha_i$’s and $\beta_j$’s in Theorem 5. It follows by Lemma 80 that the maximizers of $\Psi_1$ are permutation symmetric and correspond to Hessian maxima of $\Psi_1$. This verifies the hypotheses of Theorem 14.

**6.3.2 Proof of Lemma 79**

In this section, we outline the proof of Lemma 79. We need to find the type(s) of the fixpoints which maximize $\Psi_1$. Let $q = (q_1, q_2, q_3)$ specify the type of a fixpoint of (184) and let $r = (R_1, R_2, R_3)$, $c = (C_1, C_2, C_3)$ be the respective values of the $R_i$’s and $C_j$’s, see Definition 11. Note that the $q_i$’s are non-negative integers satisfying $q_1 + q_2 + q_3 = q$. 

144
Using Theorem 5, we obtain that the value of $\Psi_{1}(\alpha, \beta)$ corresponding to this fixpoint of (184) is given by the value of the function $\Phi_{S}$, where

$$\Phi_{S}(q, r, c) := (d + 1) \ln \left( \sum_{i=1}^{3} q_{i} R_{i} \sum_{j=1}^{3} q_{j} C_{j} + (B - 1) \sum_{i=1}^{3} q_{i} R_{i} C_{i} \right) - d \ln \left( \sum_{i=1}^{3} q_{i} R_{i}^{(d+1)/d} \right) - d \ln \left( \sum_{j=1}^{3} q_{j} C_{j}^{(d+1)/d} \right),$$

and $d = \Delta - 1$. It is a non-trivial task to directly compare the values of $\Phi_{S}$ over fixpoints of (184). Instead, we will solve a relaxed version of the problem, seeking to maximize $\Phi_{S}$ over non-negative $q_i$’s which satisfy $q_1 + q_2 + q_3 = q$. If this maximum happens to occur for integer $q$ and the respective values of $R_i$’s and $C_j$’s are solutions of (184), then we have also found the solution to the original maximization problem. It turns out that all of the above are satisfied iff $q$ is even.

To formalize the argument, for non-negative $q_i$’s such that $q_1 + q_2 + q_3 = q$, define

$$\overline{\Phi}(q) := \max_{r, c} \overline{\Phi}_{S}(q, r, c)$$

where the maximum is over $r = (R_1, R_2, R_3)^{\top}$, $c = (C_1, C_2, C_3)^{\top}$ which satisfy

$$\sum_{i=1}^{3} q_{i} R_{i} \sum_{j=1}^{3} q_{j} C_{j} + (B - 1) \sum_{i=1}^{3} q_{i} R_{i} C_{i} > 0,$$

$$R_1, R_2, R_3, C_1, C_2, C_3 \geq 0.$$  

It is simple to see that in the region (187), $\overline{\Phi}_{S}$ is well defined. It is not completely immediate that the maximum in (186) is well defined since the region (187) is not compact. This is a consequence of the following scale-free property of $\overline{\Phi}_{S}$ with respect to $r$ and $c$:

for every $c_1, c_2 > 0$ it holds that $\overline{\Phi}_{S}(q, c_{1} r, c_{2} c) = \overline{\Phi}_{S}(q, r, c)$.  

Using (188), it is simple to obtain the following.

**Lemma 81.** Let $B \geq 0$ and $q \geq 2$. For all $q_1, q_2, q_3 \geq 0$ which satisfy $q_1 + q_2 + q_3 = q$, the maximum in (186) is well defined. Moreover, the maximum of $\overline{\Phi}(q_1, q_2, q_3)$ over all such $q_1, q_2, q_3$ is attained.

We next seek to connect the maximizers of (186) with solutions of (184). To do this, we first need to consider whether the maximum in (186) happens on the boundary of the region
it turns out that the maximum can happen at the boundary $R_i = 0$ or $C_i = 0$ if $q_i$ is close to zero. While the boundary cases are an artifact of allowing $q_i$’s to be non-integer, we will need to treat them explicitly to find the maximum of $\Phi$.

**Definition 12.** A triple $q = (q_1, q_2, q_3)$ is **good** if the $r, c$ which achieve the maximum in (186) satisfy: for $i = 1, 2, 3$, $q_i > 0$ implies $R_i, C_i > 0$. A triple $q = (q_1, q_2, q_3)$ is **bad** if it is not good.

To complete the connection, we need to further restrict the set of triples $q$. To motivate this restriction, note that if we consider the region (187) in the subspace $R_1 = R_2$ and $C_1 = C_2$, we obtain $\Phi(q_1 + q_2, q_3, 0) \leq \Phi(q_1, q_2, q_3)$. To avoid degenerate cases, we consider only triples $q$ where such simple inequalities do not hold at equality.

**Definition 13.** Let $t = 2$ or 3. A triple $q = (q_1, q_2, q_3)$ is called $t$-**maximal** if exactly $t$ of the $q_i$’s are non-zero and for all distinct $i, j, k \in \{1, 2, 3\}$ it holds that $\Phi(q_i + q_j, q_k, 0) < \Phi(q)$. Our interest is in maximal good triples $q = (q_1, q_2, q_3)$. This is justified by the following lemma, whose proof is given in Section 6.3.5.

**Lemma 82.** Suppose that $q_1, q_2, q_3$ are non-negative integers and the triple $q = (q_1, q_2, q_3)$ is $t$-maximal and good. Then, the $r, c$ which achieve the maximum in (184) specify a $t$-supported fixpoint of (184) of type $(q_1, q_2, q_3)$.

Thus to prove Lemma 79, it suffices to prove that the triple $$(q/2, q/2, 0)$$ is 2-maximal and good and that the maximum of $\Phi(q)$ is achieved at $$(q/2, q/2, 0)$$. The next lemma examines which maximal good triples can be a maximum of $\Phi$.

**Lemma 83.** Let $q \geq 3$ and $0 \leq B < 1$. There do not exist 3-maximal good triples $q$ which maximize $\Phi(q)$. The only 2-maximal good triples $q$ where a maximum of $\Phi(q)$ can occur are $(q/2, q/2, 0)$ or its permutations.

Lemma 83 is not sufficient to yield Lemma 79 because the maximum of $\Phi(q)$ can occur at a bad triple $q$. This possibility is excluded by the following lemma.

**Lemma 84.** Let $q \geq 3$ and $0 \leq B < \frac{\Delta - q}{\Delta}$. There do not exist bad triples $q$ which maximize $\Phi(q)$. 

146
Using Lemmas 83 and 84, we can now give the proof of Lemma 79.

**Proof of Lemma 79.** The maximum of $\Phi(q)$ over triples $q$ is attained by Lemma 81. This maximum can happen either at a bad or a good triple $q$. Maxima at bad triples $q$ are excluded by Lemma 84. Maxima at 3-maximal good triples are excluded by the first part of Lemma 83. Thus, the maximum must happen at a (good) triple of the form $q = (q_1, q_2, 0)$. The latter can be either 2-maximal or not. If it is not 2-maximal, the maximum must equal $\Phi(q)$, which in the regime $0 \leq B < \Delta - q$ is excluded by Lemma 76. Thus, the maximum must happen at a 2-maximal good triple, which Lemma 83 asserts that it must be the triple $(q/2, q/2, 0)$. Finally, for $q$ even, by Lemma 82 the $r, c$ which achieve the maximum in (186) correspond to a 2-supported fixpoint of (184) of type $(q/2, q/2, 0)$, as wanted. □

For the proofs of Lemmas 83 and 84, we will often perturb the values of $q_i$’s. The following lemma, which is proved in Section 6.3.5 will be very helpful.

**Lemma 85.** Let $q = (q_1, q_2, q_3)$ and $I = \{i \mid q_i > 0\}$. Suppose that $r, c$ achieve the maximum in (186). Then, for $i \in I$ it holds that

$$\frac{\partial \Phi^S(q, r, c)}{\partial q_i} = \frac{R_i \sum_j q_j C_j + C_i \sum_j q_j R_j + (d - 1)(1 - B) R_i C_i}{\sum_j q_j R_j \sum_j q_j C_j + (B - 1) \sum_j q_j R_j C_j}.$$ (189)

Moreover, if there exist $i, j \in I$ such that $\frac{\partial \Phi^S}{\partial q_i} = \frac{\partial \Phi^S}{\partial q_j} \neq 0$, the maximum of $\Phi$ is not achieved at the triple $q$.

### 6.3.3 Good Triples - Proof of Lemma 83

We first prove the statement of the lemma for 3-maximal good triples $q = (q_1, q_2, q_3)$, the proof for 2-maximal good triples will easily be inferred by appropriately modifying the arguments in the special case $q_2 = 0$.

Let $q = (q_1, q_2, q_3)$ be a 3-maximal good triple. Since $q$ is 3-maximal all of the $q_i$’s are positive. Moreover, $q$ is good, and hence the maximum in (186) for $q$ is attained at positive $R_i$’s and $C_j$’s. Thus, the $R_i$’s and $C_j$’s satisfy $\partial \Phi^S / \partial R_i = \partial \Phi^S / \partial C_j = 0$ which give

$$R_i^{1/d} \propto q_1 C_1 + q_2 C_2 + q_3 C_3 + (B - 1) C_i, \quad C_j^{1/d} \propto q_1 R_1 + q_2 R_2 + q_3 R_3 + (B - 1) R_j.$$ (190)
Since \( q \) is 3-maximal, we may assume that \( r \) is such that \( R_i \neq R_j \) for all \( i \neq j \). Otherwise, if for example \( R_1 = R_2 \), by (190), we have \( C_1 = C_2 \) as well, so that \( \Phi(q_1, q_2, q_3) = \Phi(q_1 + q_2, q_3, 0) \), contradicting the 3-maximality of \( q \). Thus, we may assume a strict ordering of the \( R_i \)'s, which by (190) implies the reverse ordering of the \( C_j \)'s. Wlog, we will use the following ordering:

\[
R_1 > R_2 > R_3 > 0 \quad \text{and} \quad 0 < C_1 < C_2 < C_3. \tag{191}
\]

The following lemma, together with the second part of Lemma 85, establishes that the maximum of \( \Phi \) cannot occur at a 3-maximal triple.

**Lemma 86.** Suppose that \( R_i \)'s and \( C_j \)'s satisfy (190) and (191). If \( R_1/R_3 \neq C_3/C_1 \) then
\[
\frac{\partial \Phi}{\partial q_1} - \frac{\partial \Phi}{\partial q_3} \neq 0. \quad \text{If} \quad R_1/R_3 = C_3/C_1 \quad \text{then} \quad \frac{\partial \Phi}{\partial q_1} - \frac{\partial \Phi}{\partial q_2} \neq 0.
\]

We next give the proof of Lemma 86. We will utilize Lemma 85 by specifying a particular scaling of the \( R_i \)'s and \( C_j \)'s which will be beneficial. To do this, set

\[
r_1^d = R_1/R_3, \quad r_2^d = R_2/R_3, \quad c_2^d = C_2/C_1, \quad c_3^d = C_3/C_1. \tag{192}
\]

The \( R_i \)'s and \( C_j \)'s may be recovered from \( r_i \)'s, \( c_j \)'s using

\[
R_1 \propto r_1^d, \quad R_2 \propto r_2^d, \quad R_3 \propto 1, \quad \text{and} \quad C_1 \propto 1, \quad C_2 \propto c_2^d, \quad C_3 \propto c_3^d. \tag{193}
\]

Translating (191) into \( r_1, r_2, c_2, c_3 \) gives

\[
r_1 > r_2 > 1 \quad \text{and} \quad c_3 > c_2 > 1. \tag{194}
\]

Moreover, dividing appropriate pairs of (190), we also obtain

\[
r_1 = \frac{B + q_1 - 1 + q_2c_2 + q_3c_3^d}{q_1 + q_2c_2 + (B + q_3 - 1)c_3^d}, \quad c_3 = \frac{B + q_3 - 1 + q_2r_2^d + q_1r_1^d}{q_3 + q_2r_2^d + (B + q_1 - 1)r_1^d};
\]

\[
r_2 = \frac{q_1 + (B + q_2 - 1)c_2 + q_3c_3^d}{q_1 + q_2c_2 + (B + q_3 - 1)c_3^d}, \quad c_2 = \frac{q_3 + (B + q_2 - 1)r_2^d + q_1r_1^d}{q_3 + q_2r_2^d + (B + q_1 - 1)r_1^d}. \tag{195}
\]

It can easily be verified that this system of equations gives

\[
q_1 = \frac{(1 - B)f(r_1, c_3) + q_2 P\left\{c_2^d - c_3^d r_2^d\right\}}{P\left(r_1^d c_3^d - 1\right)}, \quad q_3 = \frac{(1 - B)f(c_3, r_1) + q_2 P\left(r_2^d - r_1^d c_2^d\right)}{P\left(r_1^d c_3^d - 1\right)}; \tag{196}
\]

\[
r_2 = \frac{r_1 c_3^d - r_2 c_3 + c_2 \left(r_2 c_3 - r_1 c_3 - 1\right)}{c_3 - 1}, \quad r_2^d = \frac{r_1^d c_3 - r_2^d c_2 \left(r_1^d c_3 - 1\right)}{c_3 - 1}. \tag{197}
\]

\[
f(x, y) := x^{d+1}y^{d+1} - x^{d}y^{d+1} - xy^{d+1} + y^{d+1} + y - 1, \quad P := (r_1 - 1)(c_3 - 1) > 0.
\]
We will need the following lemma.

Lemma 87. Assume that \(q_1, q_2, q_3, r_1, r_2, c_2, c_3\) satisfy (194), (196), (197). If \(r_1 = c_3\) then \(r_2 = c_2\) and \(q_1 = q_3\).

Proof of Lemma 87. We prove that \(r_1 = c_3\) implies \(r_2 = c_2\). Once this is done, (196) easily gives that \(r_1 = c_3\) implies \(q_1 = q_3\) as well, thus proving the lemma.

So, suppose that \(z = r_1 = c_3\) and for the sake of contradiction assume \(r_2 \neq c_2\). By (194) we obtain that \(r_2, c_2 \in (1, z)\). Eliminating \(r_2\) from (197) we obtain that \(c_2\) (and by a symmetric argument \(r_2\)) satisfies

\[
g(s) := \left(\frac{z^{d+1} - 1 - s^d(z - 1)}{z^d - 1}\right)^d + \frac{s(z^d - 1) - (z^{d+1} - 1)}{z - 1} = 0.
\]

In fact, \(g(1) = g(z) = 0\) as well, so that \(g\) has at least four distinct roots in \([1, z]\). It follows that \(g'(s) = 0\) has at least three distinct solutions in \([1, z]\), say \(s_i\) for \(i = 1, 2, 3\).

As a consequence of \(g'(s_i) = 0\), we easily obtain that the \(s_i\)'s satisfy \(h(s_i) = c\) where

\[
h(s) := (z^{d+1} - 1)s - s^{d+1}(z - 1)\]

and \(c\) is a constant which depends only on \(z, d\). Thus, \(h'(s) = 0\) has at least two distinct solutions in \([1, z]\) which is clearly absurd. \(\square\)

Proof of Lemma 86. Set

\[
DIF_{13} := \frac{\partial \Phi_S}{\partial q_1} - \frac{\partial \Phi_S}{\partial q_3}, \quad DIF_{12} := \frac{\partial \Phi_S}{\partial q_1} - \frac{\partial \Phi_S}{\partial q_2}, \quad S := \sum_i q_i R_i \sum_j q_j C_j + (B - 1) \sum_i q_i R_i C_i.
\]

We use the expressions (189) for the derivatives. The denominators in the expressions are the same, so we may ignore them. Moreover, the expressions therein are scale-free, consequently in order to write the derivatives with respect to \(r_i\)'s and \(c_j\)'s we just need to make the substitutions (193).

To prove the first part of the lemma, we eliminate \(q_1, q_3\) from the resulting expression for \(DIF_{13}\) using (196). This substitution has the beneficial effect of eliminating \(q_2, r_2\) from the final expression. After straightforward calculations, we obtain the following:

\[
DIF_{13} = -\frac{(1 - B) g(r_1, c_3)}{S(r_1 - 1)(c_3 - 1)}, \quad \text{where} \quad g(r_1, c_3) := (r_1 - c_3)(r_1^d - 1)(c_3^d - 1) - d(r_1 - 1)(c_3 - 1)(r_1^d - c_3^d).
\]

(198)
It can easily be seen that for \( r_1, c_3 > 1 \), it holds that \( g(r_1, c_3) = 0 \) iff \( r_1 = c_3 \) iff \( R_1/R_3 = C_3/C_1 \) as desired.

We next prove the second part of the lemma. Since \( R_1/R_3 = C_3/C_1 \), we have \( r_1 = c_3 \) and by Lemma 87, \( r_2 = c_2 \) and \( q_1 = q_3 \). Using these, (196) and (197) simplify to

\[
q_1 = \frac{(1 - B)(r_1^{d+1} - 1) - q_2 r_2^d (r_1 - 1)}{(r_1 - 1) (r_1^d + 1)} \quad \text{and} \quad r_2 = \frac{r_1^{d+1} - 1 - r^d_2 (r_1 - 1)}{r_1^d - 1}.
\]

Moreover, using the substitutions (193) and \( q_1 = q_3 \), we obtain

\[
DIF_{12} = \frac{(q_1 r_1^d + q_2 r_2^d + q_1)(r^d_1 - 2r^d_2 + 1) + (d - 1)(1 - B)(r^d_1 - r^d_2)}{S} = -\frac{(1 - B)\left( (d - 1)(r_1 - 1)r_2^2 + 2r_2^d (r_1^{d+1} - 1) - (r_1^{2d+1} + dr_1^{d+1} - dr_1^d - 1) \right)}{(r_1 - 1)S},
\]

where in the second equality we substituted the value of \( q_1 \) from (199). Observe that the numerator is a quadratic polynomial in \( r_2^d \) and, by inspection, for \( r_1 > 1 \), its roots are of opposite sign. Thus, \( DIF_{12} = 0 \) iff \( r_2^d = \rho_1 \), where

\[
\rho_1(r_1) := \frac{\sqrt{D} - (r_1^{d+1} - 1)}{(d - 1)(r_1 - 1)} \quad \text{and} \quad D := (dr_1^{d+1} - (d - 1)r_1^d + 1)\left( r_1^{d+1} + (d - 1)r_1 - d \right).
\]

For the sake of contradiction, suppose that \( r_2^d = \rho_2 \). Then (199) gives that \( r_2 = \rho_2 \), where

\[
\rho_2(r_1) := \frac{d (r_1^{d+1} - 1) - \sqrt{D}}{(d - 1)(r_1^d - 1)}.
\]

Thus \( \rho_1 = \rho_2^d \). We obtain a contradiction by showing that for every \( r_1 > 1 \), it holds that \( \rho_2^d < \rho_1 \) or equivalently \( d \ln \rho_2 < \ln \rho_1 \). It is easy to see that in the limit \( r_1 \downarrow 1 \) the inequality is satisfied at equality, thus it suffices to prove that the derivative of the rhs w.r.t \( r_1 \) is greater than the respective derivative of the l.h.s. for \( r_1 > 1 \).

This differentiation is cumbersome but otherwise straightforward. The final result is

\[
\frac{1}{\rho_1} \frac{\partial \rho_1}{\partial r_1} - \frac{d}{\rho_2} \frac{\partial \rho_2}{\partial r_1} = \frac{\frac{(d + 1)g(r_1)h(r_1)}{(r_1 - 1) \left( \sqrt{D} - (r_1^{d+1} - 1) \right) \left( d (r_1^{d+1} - 1) - \sqrt{D} \right)}}, \quad (200)
\]

\[
g(r_1) := r_1^{2d} - d_1^2 r_1^{d+1} + 2(d - 1) r_1^d - d_1^2 r_1^{d-1} + 1,
\]

\[
h(r_1) := (d + 1)(r_1^{d+1} - 1) - (d - 1)(r_1^d - 1) - 2\sqrt{D}.
\]

Note that the denominator in the rhs. of (200) is positive for \( r_1 > 1 \): the terms involving \( \sqrt{D} \) are positive since they are the numerators of \( \rho_1 \), \( \rho_2 \). The final part of the proof consists of proving that \( g(r_1) > 0 \) and \( h(r_1) > 0 \) for \( r_1 > 1 \).
The polynomial $g$ has 4 sign changes and hence, by the Descartes’ rule of signs has at most 4 positive roots. In fact, a tedious calculation shows that $r_1 = 1$ is a root by multiplicity 4, thus proving that $g(r_1) > 0$ for $r_1 > 1$. To prove that $h(r_1) > 0$ for $r_1 > 1$, note the identity

$$[(d + 1)(r_1^{d+1} - 1) - (d - 1)(r_1^d - 1)]^2 - 4D = (d - 1)^2(r_1 - 1)^2(r_1^d - 1)^2.$$ 

This completes the proof.

To prove the second part of Lemma 83, assume that $q = (q_1, q_2, q_3)$ is a 2-maximal good triple. Since $q$ is 2-maximal, w.l.o.g. we may assume that $q_2 = 0$. Note that the values of $R_2, C_2$ do not affect the value of the derivatives $\partial \Phi^S/\partial q_1, \partial \Phi^S/\partial q_3$ when $q_2 = 0$. Similarly, (196) continues to hold even when $q_2 = 0$. Thus, the proof of the first part of Lemma 86 carries through verbatim. In particular, if $R_1/R_3 \neq C_3/C_1$, then $\partial \Phi^S/\partial q_1 - \partial \Phi^S/\partial q_3 \neq 0$. By the second part of Lemma 85, it follows that $q = (q_1, 0, q_3)$ cannot be a maximum unless $R_1/R_3 = C_3/C_1$. In this case, (196) gives $q_1 = q_3$. Since $q_1 + q_3 = q$, we obtain that the only 2-maximal good triples where the maximum of $\Phi$ may occur are $(q/2, q/2, 0)$ or its permutations, as desired.

This concludes the proof of Lemma 83.

### 6.3.4 Bad Triples - Proof of Lemma 84

To get a handle on bad triples, we first give necessary conditions so that the maximum in (186) happens at the boundary. The proof of the following lemma is given in Section 6.3.5.

**Lemma 88.** Let $0 \leq B < 1$. For a triple $q = (q_1, q_2, q_3)$, let $r, c$ achieve the maximum in (186). Then, if $q_i > 0$, the following implications hold:

$$R_i = 0 \Rightarrow \sum_j q_j C_j \leq (1 - B)C_i, \quad C_i = 0 \Rightarrow \sum_j q_j R_j \leq (1 - B)R_i.$$ 

In particular, if $q_i > 1 - B$ it holds that $R_i, C_i > 0$ and hence for every $q \geq 3$ there exists $i$ such that $R_i, C_i > 0$.

We next examine bad triples. Note that a bad triple $q = (q_1, q_2, q_3)$, by the second part of Lemma 85, must have at least two positive entries. We consider cases whether the triple
\( \mathbf{q} \) has two or three positive entries. We start with the case where exactly two of the \( q_i \)'s are positive. We assume throughout the rest of the section that \( \mathbf{r}, \mathbf{c} \) achieve the maximum in (186).

Let \( \mathbf{q} = (q_1, q_2, 0) \) be a bad triple where \( q_1, q_2 > 0 \). Since \( \mathbf{q} \) is bad, at least one of \( R_1, R_2, C_1, C_2 \) is zero. Wlog, we may assume \( C_2 = 0 \). By the second part of Lemma 88, it follows that \( R_1, C_1 > 0 \). There are two cases to consider.

(I) \( R_2 = 0 \), (II) \( R_2 > 0 \).

Case (I) is straightforward: by the first part of Lemma 85, we trivially have \( \partial \Phi_S / \partial q_1 > 0 \) and \( \partial \Phi_S / \partial q_2 = 0 \), so that the second part of Lemma 85 yields that \( \mathbf{q} \) does not maximize \( \Phi \).

We next examine case (II). Since \( \Phi_S \) is scale-free (see (188)), we may assume that \( C_1 = 1 \). Since \( R_1, R_2 \) are positive, it holds that \( \partial \Phi_S / \partial R_1 = \partial \Phi_S / \partial R_2 = 0 \), yielding

\[
R_1 \propto y^d, \ R_2 \propto 1, \ \text{where} \ y = (q_1 + B - 1)/q_1.
\]

Expressing \( q_1, q_2 \) in terms of \( y \) and substituting in \( \Phi_S \), we obtain the value of \( \Phi(\mathbf{q}) \):

\[
\Phi(\mathbf{q}) = \log h(y), \ \text{where} \ h(y) := \frac{(1 - B) (q(1 - y) - (1 - B)(1 - y^{d+1}))}{(1 - y)^2}.
\]

Let \( I \) be the interval \([0, (q + B - 1)/q]\). Note that for any \( y \in I \), there exists a positive \( q_1 \in [0, q] \) such that \( y = (q_1 + B - 1)/q_1 \). Obviously, if \( \mathbf{q} \) maximizes \( \Phi \), it must be the case that \( y \) maximizes \( h(y) \) in the interval \( I \). We compute \( h'(y) \).

\[
h'(y) = \frac{(1 - B) r(y)}{(1 - y)^3}, \ \text{where} \ r(y) := q(1 - y) - (1 - B)((d - 1)y^{d+1} - (d + 1)y^d + 2).
\]

It is immediate to see that \( r(y) \) is convex for \( y \in [0, 1] \). Since \( r(0) = q - 2(1 - B) > 0 \) and \( r(1) = 0 \), we obtain that either

(i) \( r(y) > 0 \) for all \( y \in I \), or 

(ii) \( \exists y_o \in I: r(y_o) = 0, r(y) > 0 \) iff \( y < y_o \).

In case (i), \( h(y) \) is increasing and hence \( h(y) \) is maximized at \( y = (q + B - 1)/q \). This value of \( y \) corresponds to \( q_1 = q \) and thus \( \Phi(\mathbf{q}) = \Phi(q, 0, 0) \).
In case (ii), we have \( h(y) \leq h(y_o) \). The value of \( q_1 \) corresponding to \( y_o \) is \( q_o := (1 - B)/(1 - y_o) \). We will show that the maximum in (186) does not happen at the boundary \( C_2 = 0 \) when \( q = (q_o, q - q_o, 0) \), implying that \( h(y_o) \) does not equal \( \Phi(q) \) and hence the maximum of \( \Phi \) as well. To prove the former, we utilize the first part of Lemma 88. In particular, we prove that

\[
q_o y_o^d + (q - q_o) > (1 - B). 
\]

(202)

Note that \( r(y_o) = 0 \) yields \( q = (1 - B)((d - 1)y_o^{d+1} - (d + 1)y_o^d + 2)/(1 - y_o) \). Plugging this expression into (202), we only need to show that

\[
\frac{(d - 1)y_o^{d+1} - dy_o^d + 1}{1 - y_o} > 1 \text{ or } (d - 1)y_o^d + 1 > dy_o^{d-1},
\]

(203)

which holds by the AM-GM inequality for any positive \( y_o \neq 1 \).

Let \( q = (q_1, q_2, q_3) \) be a bad triple where all of the \( q_i \)'s are positive. Since \( q \) is bad, at least one of the \( R_i \)'s and \( C_j \)'s is zero. W.l.o.g. we may assume \( C_2 = 0 \). Moreover, by the second part of Lemma 88, we may also assume that \( R_1, C_1 > 0 \). There are four cases to consider.

(I) \( R_2 = 0 \),  (II) \( R_2, R_3 > 0, C_3 = 0 \),  (III) \( R_2, R_3, C_3 > 0 \),  (IV) \( R_2, C_3 > 0, R_3 = 0 \).

We omitted the case \( R_2 > 0 \) and \( R_3 = C_3 = 0 \), which is identical to case (I) after renaming the \( q_i \)'s.

Case (I) is straightforward: since \( R_2 = C_2 = 0 \), (189) gives \( \partial \Phi^S/\partial q_2 = 0 \). Since at least one of \( \partial \Phi^S/\partial q_1, \partial \Phi^S/\partial q_3 \) is positive, the second part of Lemma 85 yields that \( q \) does not maximize \( \Phi \).

We next examine case (II). Since \( \Phi^S \) is scale-free (see (188)), we may substitute \( C_1 = 1 \). Setting the derivatives of \( \partial \Phi^S/\partial R_1, \partial \Phi^S/\partial R_2, \partial \Phi^S/\partial R_3 \) equal to zero, we obtain

\[
R_1 \propto (q_1 + B - 1)^d/q_1^d, \quad R_2 \propto 1, \quad R_3 \propto 1.
\]

It follows that \( \Phi(q) = \Phi(q_1, q_2 + q_3, 0) \) and hence the maximum of \( \Phi \) does not occur at \( q \) by the argument for case (II) in (201).
We next examine case (III). The partial derivatives of $\Phi$ with respect to $R_1, R_2, R_3, C_1, C_3$ must vanish so we obtain

$$
R_1^{1/d} \propto q_1 C_1 + q_2 C_3 - (1 - B) C_1, \quad R_2^{1/d} \propto q_1 C_1 + q_3 C_3, \quad R_3^{1/d} \propto q_1 C_1 + q_3 C_3 - (1 - B) C_3, \quad (204)
$$

$$
C_1^{1/d} \propto q_1 R_1 + q_2 R_2 + q_3 R_3 - (1 - B) R_1, \quad C_3^{1/d} \propto q_1 R_1 + q_2 R_2 + q_3 R_3 - (1 - B) R_3.
$$

If $C_1 = C_3$, then $R_1 = R_3$ and thus we obtain $\overline{\Phi}(q_1, q_2, q_3) = \overline{\Phi}(q_1 + q_3, q_2, 0)$, contradicting the maximality of $q$ by the argument for case (II) in (201). Thus, wlog we may assume $C_1 < C_3$. By (204), this yields

$$
R_2 > R_1 > R_3, \quad C_1 < C_3. \quad (205)
$$

We have the following analogue of Lemma 86, which proves that the maximum cannot occur at $q$ by the second part in Lemma 85.

**Lemma 89.** Suppose that $R_i$’s and $C_j$’s satisfy (204) and (205). If $R_1/R_3 \neq C_3/C_1$ then $\frac{\partial \Phi^S}{\partial q_1} - \frac{\partial \Phi^S}{\partial q_3} \neq 0$. If $R_1/R_3 = C_3/C_1$ then $\frac{\partial \Phi^S}{\partial q_1} - \frac{\partial \Phi^S}{\partial q_2} \neq 0$.

**Proof of Lemma 89.** The proof is analogous to the proof of Lemma 86, we highlight the main differences. Let $r_{d1} = R_1/R_3, r_{d2} = R_2/R_3, c_{d3} = C_3/C_1$. The $R_i$’s and $C_j$’s may be recovered by the $r_i$’s and $c_j$’s by

$$
R_1 \propto r_{d1}, R_2 \propto r_{d2}, R_3 \propto 1, \quad C_1 \propto 1, C_3 \propto c_{d3}. \quad (206)
$$

By (205), we have

$$
r_2 > r_1 > 1 \quad \text{and} \quad c_3 > 1.
$$

The expressions for $r_1, r_2, c_3$ in (195) are exactly the same after substituting $c_2 = 0$. The same is true for (196), (197). It follows that the proof for the first part of Lemma 86 holds verbatim in this case as well (note that the ordering of $r_1, r_2$ is different here but that part of the argument does not use the ordering).

While the proof for the second part of Lemma 86 does not carry through as simply, the changes are minor. We assume that $r_1 = c_3$ and set $DIF_{12} := \frac{\partial \Phi^S}{\partial q_1} - \frac{\partial \Phi^S}{\partial q_2}$. Plugging $r_1 = c_3$ and $c_2 = 0$ in (196), (197) and then substituting the resulting expressions in $DIF_{12}$
Proof of Lemma 90. The approach for the first part is similar the proof of Lemma 86. Set

\[ DIF_{12} = \frac{(1 - B) h(r_1)}{r_1 - 1}, \text{ where } h(r_1) := (r_1^{d+1} + dr_1^{d+1} - dr_1^d - 1) - \frac{(r_1^{d+1} - 1)^{d+1}}{(r_1^d - 1)^d}. \]

By a first derivative argument, the function

\[ g(r_1) := \log \left( \frac{(r_1^{d+1} - 1)^{d+1}}{(r_1^d - 1)^d (r_1^{2d+1} + dr_1^{d+1} - dr_1^d - 1)} \right), \]

is strictly increasing for \( r_1 > 1 \). Thus, \( g(r_1) \geq g(+\infty) = 0 \), which gives \( h(r_1) > 0 \) for all \( r_1 > 1 \). This proves that \( DIF_{12} \neq 0 \), as desired.

Finally, we examine case (IV). The partial derivatives of \( \overline{\Phi^S} \) with respect to \( R_1, R_2, C_1, C_3 \) must vanish so we obtain

\[
R_1^{1/d} \propto q_1 C_1 + q_3 C_3 - (1 - B) C_1, \quad R_2^{1/d} \propto q_1 C_1 + q_3 C_3, \\
C_1^{1/d} \propto q_1 R_1 + q_2 R_2 - (1 - B) R_1, \quad C_3^{1/d} \propto q_1 R_1 + q_2 R_2.
\]

(207)

Note that we have \( R_1 < R_2 \) and \( C_1 < C_3 \).

**Lemma 90.** If \( R_2/R_1 \neq C_3/C_1 \) then either \( \frac{\partial \overline{\Phi^S}}{\partial q_2} - \frac{\partial \overline{\Phi^S}}{\partial q_3} \neq 0 \) or \( \frac{\partial \overline{\Phi^S}}{\partial q_1} - \frac{\partial \overline{\Phi^S}}{\partial q_2} \neq 0 \). If \( R_2/R_1 = C_3/C_1 \) and \( \frac{\partial \overline{\Phi^S}}{\partial q_1} - \frac{\partial \overline{\Phi^S}}{\partial q_2} = 0 \), then the maximum in (186) does not happen at the boundary \( C_2 = 0 \).

**Proof of Lemma 90.** The approach for the first part is similar the proof of Lemma 86. Set \( r_2^d = R_2/R_1 \) and \( c_3^d = C_3/C_1 \), so that \( r_1, c_3 > 1 \). Dividing appropriate pairs in (207), we obtain

\[
r_2 = \frac{q_1 + q_3 c_3^d}{(q_1 + B - 1) + q_3 c_3^d}, \quad c_3 = \frac{q_1 + q_2 r_2^d}{(q_1 + B - 1) + q_2 r_2^d}. 
\]

(208)

It follows that

\[
q_2 = \frac{q_1 - (q_1 + B - 1) c_3}{r_2^d (c_3 - 1)}, \quad q_3 = \frac{q_1 - (q_1 + B - 1) r_2}{c_3^d (r_2 - 1)}.
\]

Using these, we obtain

\[
\frac{\partial \overline{\Phi^S}}{\partial q_2} - \frac{\partial \overline{\Phi^S}}{\partial q_3} = 0 \Rightarrow f(r_2) = f(c_3), \text{ where } f(x) := \frac{x^{d+1}}{x - 1}, 
\]

(209)

\[
\frac{\partial \overline{\Phi^S}}{\partial q_1} - \frac{\partial \overline{\Phi^S}}{\partial q_3} = 0 \Rightarrow r_2^{d+1} (c_3 - 1) - (d + 1) r_2 c_3 + d(r_2 + c_3) - (d - 1) = 0.
\]

(210)
It is relatively simple to prove that this cannot be the case unless \( r_2 = c_3 \). This gives the first part.

For the second part, we have \( r_2 = c_3 \) and \( \frac{\partial \Phi}{\partial q_1} - \frac{\partial \Phi}{\partial q_3} = 0 \). Thus, (210) yields

\[
r_2^{d+1} = (d + 1)r_2 - (d - 1).
\] (211)

To prove that the maximum does not happen at the boundary \( C_2 = 0 \), we use the first part of Lemma 88. It suffices to prove that

\[
q_1 + q_2 r_2^d > (1 - B)r_2^d.
\] (212)

We have that \( q_2 = q_3 = (q - q_1)/2 \), so that (208) gives

\[
q_1 = \frac{q(r_2^{d+1} - r_2^d) - 2r_2(1 - B)}{(r_2 - 1)(r_2^d - 2)}, \quad q_2 = q_3 = \frac{q - r_2(q + B - 1)}{(r_2 - 1)(r_2^d - 2)}.
\] (213)

Plugging (213) into (212) gives the equivalent inequality

\[
\frac{(1 - B)(r_2^d + r_2 - r_2^{d+1})}{r_2 - 1} > 0
\]

To see the latter, use (211) to obtain

\[
r_2^d + r_2 - r_2^{d+1} = r_2^d + (d - 1) - dr_2 > 0, \quad \text{for all } r_2 > 1 \text{ by the AM-GM inequality.}
\]

This completes the proof. \( \square \)

### 6.3.5 Remaining Proofs

**Proof of Lemma 78.** Let \( R_i = r_i^d, C_i = c_i^d, r = \sum_{i=1}^q r_i^d \), and \( c = \sum_{i=1}^q c_i^d \). We have

\[
r_i = c - (1 - B)c_i^d \quad \text{and} \quad c_i = r - (1 - B)r_i^d.
\]

It is clear from this equation that \( R_i = R_j \) iff \( C_i = C_j \) and hence also \( t_R = t_C \). We also obtain that for \( i = 1, \ldots, q \),

\[
r_i = c - (1 - B)(r - (1 - B)r_i^d).
\] (214)

Since \( r \) is the sum of \( r_i^d \) and the \( r_i \) are positive, we have \( (1 - B)r_i^d < r \). Fix the values of \( r, c \) and let \( I \) be the interval where \( (1 - B)x^d < r \). Using (214), we shall prove that \( t_R \leq 3 \)
by arguing that \( f(x) = c - (1 - B)(r - (1 - B)x^d)^d - x \) has at most 3 positive roots in the interval \( I \), counted by multiplicities. We have

\[
f'(x) = (1 - B)^2d^2(r - (1 - B)x^d)^{d-1}x^{d-1} - 1 = \left(\sum_{i=0}^{d-2} g(x)^i\right)(g(x) - 1),
\]

where

\[
g(x) = \left((1 - B)d\right)^{2/(d-1)}(r - (1 - B)x^d)x.
\]

Note that \( g(x) > 0 \) in the interval \( I \) and hence all roots of \( f'(x) \) in this interval come from \( g(x) - 1 \). The polynomial \( g(x) - 1 \) has at most two positive roots by Descartes’ rule of signs, hence \( f'(x) \) has at most two positive roots in \( I \). Thus, \( f(x) \) has at most three positive roots in \( I \), all roots counted by their multiplicities. This concludes the proof.

**Proof of Lemma 80.** Let \( q' = q/2 \). To better align with the results of Section 6.3.3, let us assume that the fixpoint \( (q', 0, q') \) maximizes \( \Psi_1 \). In Section 6.3.3, we proved that this can be the case only if \( R_1/R_3 = C_3/C_1 \) or (in the parameterization of Section 6.3.3) \( r_1 = c_3 =: x \) where \( x > 1 \). Equation (195) for \( q_2 = 0, q_1 = q_3 = q' \) gives that \( x \) satisfies

\[
x = \frac{B + q' - 1 + q'x^d}{q' + (B + q' - 1)x^d}.
\]

It is straightforward to check that (215) has exactly one solution \( x > 1 \) for all \( 0 \leq B < \frac{\Delta - q}{\Delta} \).

The values of \( R_1, C_1, R_3, C_3 \) may be recovered by (193), which in the case \( q_2 = 0 \) give

\[
R_1 \propto x^d, R_3 \propto 1 \text{ and } C_1 \propto 1, C_3 \propto x^d.
\]

This proves the second part of the lemma. For the first part, to check Jacobian stability, we proceed as in the proof of Lemma 76. The eigenvalues of the matrix \( L \) in this case can be computed easily as well. They are given by \( \pm 1 \) by multiplicity 1, \( \pm \lambda_1 \) by multiplicity \( q - 2 \) and \( \pm (B + q - 1)\lambda_2^2 \) by multiplicity 1, where

\[
\lambda_1 := \frac{(1 - B)x^{d/2}}{\sqrt{(q' + (B + q' - 1)x^d)(B + q' - 1 + q'x^d)}}.
\]

To prove that the absolute value of the eigenvalues different from 1 is less than \( 1/d \), it suffices to prove that \( \lambda_1 < 1/d \). Use (215) to solve for \( q' \) and plug the value into the expression for \( \lambda_1 \). This yields that \( \lambda_1 \) is equal to \( x^{(d-1)/2}(x - 1)/(x^d - 1) \), which by the AM-GM inequality is less than \( 1/d \) for \( x > 1 \).
Proof of Lemma 81. For non-negative $\mathbf{q} = (q_1, q_2, q_3)$ with $q_1 + q_2 + q_3 = q$, consider the function
\[
\overline{F}(\mathbf{q}) = \max_{\mathbf{r}, \mathbf{c}} F(\mathbf{q}, \mathbf{r}, \mathbf{c}), \text{ where } F(\mathbf{q}, \mathbf{r}, \mathbf{c}) := \sum_{i=1}^{3} q_i R_i \sum_{j=1}^{3} q_j C_j + (B - 1)\sum_{i=1}^{3} q_i R_i C_i,
\] (216)
and the maximum is over the compact region (by restricting to $R_i = C_i = 0$ whenever $q_i = 0$)
\[
\sum_{i=1}^{3} q_i R_i^{(d+1)/d} \leq 1, \quad \sum_{j=1}^{3} q_j C_j^{(d+1)/d} \leq 1,
\] (217)
\[R_1, R_2, R_3, C_1, C_2, C_3 \geq 0.\]
Note that $\overline{F}(\mathbf{q}) > 0$, since we can set all of the $R_i$’s and $C_j$’s equal to $x$, where $q x^{(d+1)/d} = 1$.
Clearly, $\overline{\Phi}(\mathbf{q}) \geq \ln \overline{F}(\mathbf{q})$. Since $\overline{\Phi}^S(\mathbf{q}, \mathbf{r}, \mathbf{c})$ is scale-free with respect to $\mathbf{r}$ and $\mathbf{c}$ (see (188)), we may scale $\mathbf{r}, \mathbf{c}$ to satisfy (217) and hence $\overline{\Phi}(\mathbf{q}) = \sup_{\mathbf{r}, \mathbf{c}} \overline{\Phi}^S(\mathbf{q}, \mathbf{r}, \mathbf{c}) \leq \ln F(\mathbf{q})$, proving that $\overline{\Phi}(\mathbf{q}) = \ln \overline{F}(\mathbf{q})$ and consequently the supremum is attained.

To prove that $\sup_{\mathbf{q}} \overline{\Phi}(\mathbf{q})$ is attained, it clearly suffices to prove that $L := \sup_{\mathbf{q}} \overline{F}(\mathbf{q})$ is attained. This can be accomplished by using variants of Berge’s Maximum Theorem [4] and showing that the function $\overline{F}(\mathbf{q})$ is upper semi-continuous. We give a more direct argument, which is similar to the proof of Berge’s Maximum Theorem and can also easily be adapted to show that $\overline{F}(\mathbf{q})$ is upper semi-continuous.

Note first that $L < \infty$ by a simple application of Hölder’s inequality. Let $\mathbf{q}_n$ be such that $\overline{F}(\mathbf{q}_n) \uparrow L$. Since the $\mathbf{q}_n$ lie in a compact region, by restricting to a subsequence we may assume that $\mathbf{q}_n \to \mathbf{q}$. Let $\mathbf{r}_n, \mathbf{c}_n$ be maximizers for $\overline{F}(\mathbf{q}_n)$ in (216). Suppose first that $\mathbf{q}$ has positive entries. Then, for sufficiently large $n$, the maximizers $\mathbf{r}_n, \mathbf{c}_n$ lie in a compact set and hence a standard diagonalisation argument yields a convergent subsequence $(\mathbf{q}_{n_k}, \mathbf{r}_{n_k}, \mathbf{c}_{n_k}) \to (\mathbf{q}, \mathbf{r}, \mathbf{c})$. By continuity, $\mathbf{r}, \mathbf{c}$ must lie in the region (217) defined by $\mathbf{q}$ and moreover $\overline{F}(\mathbf{q}_{n_k}) = F(\mathbf{q}_{n_k}, \mathbf{r}_{n_k}, \mathbf{c}_{n_k}) \to F(\mathbf{q}, \mathbf{r}, \mathbf{c})$. Thus $L = F(\mathbf{q}, \mathbf{r}, \mathbf{c})$ and the supremum is attained.

Assume now that $\mathbf{q}$ has an entry equal to zero, say $q_1$, so that $q_{1n} \to 0$ (with the natural notation for entries of the subsequences). In this setting, $R_{1n}, C_{1n}$ might escape to infinity, so assume that $R_{1n}, C_{1n} \uparrow \infty$, by restricting to a subsequence if necessary. However, (217) implies $q_{1n} R_{1n}^{(d+1)/d}, q_{1n} C_{1n}^{(d+1)/d} \leq 1$ and hence $q_{1n} R_{1n}, q_{1n} C_{1n} \to 0$. Note
that \( q_{1n}R_{1n}C_{1n} \to 0 \) as well; otherwise there exists a subsequence with \( q_{1n_k}R_{1n_k}C_{1n_k} \geq \epsilon > 0 \). This contradicts that \( r_{n_k}, c_{n_k} \) maximize \( F(q_{n_k}, \cdot, \cdot) \), since setting \( R_{1n_k} = C_{1n_k} = 0 \) would maintain feasibility in (217) and achieve a bigger value of \( F \) for all sufficiently large \( k \) (recall that \( B < 1 \)). Thus \( q_{1n}R_{1n}, q_{1n}C_{1n}, q_{1n}R_{1n}C_{1n} \to 0 \), yielding once again \( L = F(q, r, c) \).

\[ \square \]

**Proofs of Lemmas 82 and 85.** We first prove Lemma 85. Let \( I_R = \{ i \in I \mid R_i > 0 \} \). For \( i \in I_R \), it must hold that \( \partial \Phi^S / \partial R_i = 0 \). Since \( q_i > 0 \) for \( i \in I \), it follows that

\[ R_i^{1/d} \propto \sum_j q_j C_j - (1 - B)C_i \quad \text{for all} \ i \in I_R, \tag{218} \]

and hence

\[ R_i^{(d+1)/d} \propto R_i(\sum_j q_j C_j - (1 - B)C_i) \quad \text{for all} \ i \in I. \]

Thus, for \( i \in I \) it holds that

\[ \frac{R_i^{(d+1)/d}}{\sum_j q_j R_j^{(d+1)/d}} = \frac{R_i(\sum_j q_j C_j - (1 - B)C_i)}{\sum_j q_j R_j \sum_j q_j C_j + (B - 1)\sum_j q_j R_j C_j}; \tag{219} \]

and an analogous argument for the \( C_i \)'s gives

\[ \frac{C_i^{(d+1)/d}}{\sum_j q_j C_j^{(d+1)/d}} = \frac{C_i(\sum_j q_j R_j - (1 - B)R_i)}{\sum_j q_j R_j \sum_j q_j C_j + (B - 1)\sum_j q_j R_j C_j}. \tag{220} \]

Moreover, by a direct calculation we have

\[ \frac{\partial \Phi^S}{\partial q_i} = (d + 1)(R_i \sum j q_j C_j + C_i \sum j q_j R_j + (B - 1)R_i C_i) - \frac{dR_i^{(d+1)/d}}{\sum_j q_j R_j^{(d+1)/d}} - \frac{dC_i^{(d+1)/d}}{\sum_j q_j C_i^{(d+1)/d}}. \tag{221} \]

Plugging (219), (220) in (221) proves the first part of Lemma 85.

For the second part of Lemma 85, assume w.l.o.g. that \( q_1, q_2 > 0 \) and \( \frac{\partial \Phi^S}{\partial q_1} - \frac{\partial \Phi^S}{\partial q_2} > 0 \). For \( \epsilon > 0 \), consider \( q' = (q_1 + \epsilon, q_2 - \epsilon, q_3) \). Since \( q_1, q_2 \) are positive, for small enough \( \epsilon \), \( q' \) has positive entries which sum to \( q \). Moreover, for small enough \( \epsilon \) the value of \( \Phi^S \) increases, while still maintaining feasibility in the region (187). Hence, \( q \) does not maximize \( \Phi \), as desired.

Lemma 82 follows easily: just use (218) and the fact that \( q_1, q_2, q_3 \) are integers to get the alignment with (184).  

\[ \square \]
Proof of Lemma 88. Suppose that $q_i > 0$ and $\sum_j q_j C_j > (1 - B) C_i$. We look at the derivative $\partial \Phi^S / \partial R_i$ evaluated at $R_i = 0$:

$$
\frac{\partial \Phi^S}{\partial R_i} = \frac{q_i (q_1 C_1 + q_2 C_2 + q_3 C_3 -(1-B) C_i)}{\sum_j q_j C_j} > 0
$$

Thus, increasing the value of $R_i$ by a sufficiently small amount, we increase the value of $\Phi^S$. Hence, the maximum cannot be obtained at the boundary $R_i = 0$. The second part of the lemma follows immediately from the first part.

6.3.5.1 Uniqueness of semi-translation invariant measures (Antiferromagnetic Potts)

In this section, we prove Lemma 75. As noted earlier, the proof extends the respective argument in [7] for colorings in the antiferromagnetic Potts model setting. That said, the technical details, due to the soft contraints, are relatively more intricate.

Proof of Lemma 75. We may assume that $R_1 \geq \ldots \geq R_q$. Then the equations easily imply $C_1 \leq \ldots \leq C_q$. Define

$$
\alpha = \frac{R_1}{R_q}, \quad \beta = \frac{R_1 + \ldots + R_{q-1}}{(q-1) R_q}, \quad S = R_1 + \ldots + R_{q-1}.
$$

We clearly have $\alpha \geq \beta \geq 1$, and we may assume for the sake of contradiction that $\beta > 1$. Note that

$$
\alpha^{1/d} = \left( \frac{R_1}{R_q} \right)^{1/d} = 1 + \frac{(1-B)(C_q - C_1)}{C_1 + \ldots + C_{q-1} + BC_q}.
$$

$$
C_q = (R_1 + \ldots + R_{q-1} + BR_q)^d = [(q-1)\beta + B]^d R_q^d
$$

$$
C_1 = (BR_1 + R_2 + \ldots + R_q)^d = [(q-1)\beta + 1 - (1-B)\alpha]^d R_q^d
$$

Moreover, by Holder’s inequality or otherwise, we have

$$
C_1 + \ldots + C_{q-1} + BC_q = \sum_{i=1}^{q-1} \left[ S + R_q - (1-B)R_i \right]^d + B(S + BR_q)^d
$$

$$
\geq (q-1) \left[ \frac{q-2 + B}{q-1} S + (q-1)R_q \right]^d + B(S + BR_q)^d
$$

$$
= (q-1) \left[ (q-2 + B)\beta + 1 \right]^d R_q^d + B[(q-1)\beta + B]^d R_q^d.
$$
Thus, we obtain that every solution must satisfy
\[
\alpha^{1/d} \leq 1 + \frac{(1 - B)\left\{[(q - 1)\beta + B]^d - [1 - (1 - B)\alpha + (q - 1)\beta]^d\right\}}{\left((q - 1)[(q - 2 + B)\beta + 1]^d + B[(q - 1)\beta + B]^d\right)} 
\iff 
0 \leq 1 - \alpha^{1/d} + \frac{(1 - B)\left[1 - \left(1 - \frac{(1-B)(\alpha-1)}{(q-1)\beta+B}\right)^d\right]}{\left((q - 1)\left[1 - \frac{(1-B)(\beta-1)}{(q-1)\beta+B}\right]^d + B\right)} =: f(\alpha, \beta, B).
\]

To obtain a contradiction, our goal is to prove that for \(q\) and \(B\) as in the statement of the lemma, when \((q - 1)\beta > \alpha \geq \beta > 1\), it holds that \(f(\alpha, \beta, B) < 0\).

It is easy to see that \(f\) is decreasing in \(B\). This immediately yields the lemma for \(q \geq \Delta\): it holds that \(f(\alpha, \beta, B) \leq f(\alpha, \beta, 0) < 0\), since the last inequality was proved by [7]. For \(q \leq d\) and \(B \geq \frac{d+1-q}{d+1} := B_c\), this yields
\[
f(\alpha, \beta, B) \leq f(\alpha, \beta, B_c) =: g(\alpha, \beta).
\]

We first prove that \(g(\alpha, \beta) \leq g(\beta, \beta)\). For \(q = 2\) there is nothing to prove. Hence we may assume that \(d \geq q \geq 3\). Clearly it suffices to prove that \(g\) is decreasing in \(\alpha\). This requires a fair bit of work, so we state it as a Lemma to prove later.

**Lemma 91.** For \(d \geq q \geq 3\) and \(B_c = \frac{d+1-q}{d+1}\), the function \(g(\alpha, \beta)\) is decreasing in \(\alpha\) for \(\alpha \geq \beta > 1\).

We finish the proof by showing that for \(\beta \geq 1\), it holds that \(g(\beta, \beta) \leq 0\) with equality iff \(\beta = 1\). After massaging the inequality, this reduces to
\[
1 \leq \left[1 - \frac{(1 - B_c)(\beta - 1)}{(q - 1)\beta + B_c}\right]^d \left[(q - 1)\left(\beta^{1/d} - 1\right) + 1 - B_c\right] + B_c\beta^{1/d} =: h(\beta)
\]

Note that the inequality holds at equality for \(\beta = 1\), so it suffices to prove \(h'(\beta) > 0\) for \(\beta > 1\), which is the assertion of the next lemma.

**Lemma 92.** For \(d \geq q \geq 2\) and \(B_c = \frac{d+1-q}{d+1}\), the function \(h(\beta)\) is increasing for \(\beta \geq 1\).

Modulo the proofs of Lemmas 91 and 92, which are given below, the proof is complete.
Proof of Lemma 91. We compute
\[
\frac{\partial g}{\partial \alpha} = -\frac{1}{d^\alpha} - (d-1)/d + \frac{(1 - B_c)^2}{(q-1)\beta + B_c} \cdot \frac{d}{(q-1)} \frac{1 - (1 - B_c)(\alpha - 1)}{(q-1)\beta + B_c}^{d-1} + B_e
\]
Let \( F(x) = x \left[ 1 - \frac{(1 - B_c)(x-1)}{(q-1)\beta + B_c} \right]^d \) for \( x \in [\beta, (q-1)\beta] \). Straightforward manipulations show that \( \frac{\partial g}{\partial \alpha} < 0 \) is equivalent to
\[
d^2(1 - B_c)^2 F(\alpha)^{(d-1)/d} \leq [(q-1)\beta + B_e] \left[ (q-1) \left( 1 - \frac{(1 - B_c)(\beta - 1)}{(q-1)\beta + B_c} \right)^d + B_e \right]. \tag{222}
\]
We prove that \( F(x) \) is decreasing in \([\beta, (q-1)\beta]\). It is simple to check that
\[
F'(x) = \left[ 1 - \frac{(1 - B_c)(x-1)}{(q-1)\beta + B_c} \right]^{d-1} \frac{(q-1)\beta + 1 - (d+1)(1 - B_c)x}{(q-1)\beta + B_e}.
\]
For \( x \in [\beta, (q-1)\beta] \), we have \((d+1)(1 - B_c)x = qx = (q-1)x + x > (q-1)\beta + 1\), where in the last inequality we used that \( \beta > 1 \). It follows that \( F(x) \) is indeed decreasing and thus \( F(\alpha) \leq F(\beta) \).

To prove (222), it thus suffices to argue that for \( \beta > 1 \) it holds
\[
d^2(1 - B_c)^2 F(\beta)^{(d-1)/d} \leq [(q-1)\beta + B_e] \left[ (q-1) \left( 1 - \frac{(1 - B_c)(\beta - 1)}{(q-1)\beta + B_c} \right)^d + B_e \right]. \tag{223}
\]
Note that \( q - 1 + B_e = d(1 - B_e) \) so that the inequality is tight for \( \beta = 1 \). By the weighted AM-GM inequality on \( A^d \) and \( 1 \) with weights \((q-1) \) and \( B_e \) respectively, we obtain
\[
(q-1)A^d + B_e \geq (q-1 + B_e)A^{d(q-1)/(q-1+B_e)} = d(1 - B_e)A^{(q-1)(d+1)/q}.
\]
We use this for \( A = \left( 1 - \frac{(1 - B_c)(\beta - 1)}{(q-1)\beta + B_c} \right)^d \) so that, after simplifications, it suffices to show that
\[
d(1 - B_c)\beta^{(d-1)/d} \leq \left[ (q-1)\beta + B_e \right] \left[ 1 - \frac{(1 - B_c)(\beta - 1)}{(q-1)\beta + B_c} \right]^{-(d+1-2q)/q}.
\]
This can further be massaged into
\[
G(\beta) := \beta^{(d-1)/d} \left[ (q-1)\beta + B_e \right]^{-(d+1-2q)/q} \left[ (q - 2 + B_c)\beta + 1 \right]^{(d+1-2q)/q} \leq \frac{1}{d(1 - B_e)}.
\]
Once again, note that the inequality holds at equality for \( \beta = 1 \), so it suffices to prove that \( G'(\beta) < 0 \) for \( \beta > 1 \). This has nothing special, apart from tedious, but otherwise
straightforward, calculations. We include the details briefly. Differentiating $\ln G(\beta)$, we obtain

$$G'(\beta) = \frac{(d - 1)}{d\beta} - \frac{(d + 1 - q)(q - 1)}{q[(q - 1)\beta + B_c]} + \frac{(d + 1 - 2q)(q - 2 + B_c)}{q[(q - 2 + B_c)\beta + 1]}.$$ 

By clearing denominators, it suffices to check that the following second order polynomial $p(\beta)$ is negative whenever $\beta > 1$:

$$p(\beta) := (d - 1)q[(q - 1)\beta + B_c][(q - 2 + B_c)\beta + 1] - (d + 1 - q)(q - 1)d\beta[(q - 1)\beta + B_c]$$

$$+ (d + 1 - 2q)(q - 2 + B_c)\beta[(q - 1)\beta + B_c].$$

Using again that $q - 1 + B_c = d(1 - B_c)$ it is easy to verify that $p(1) = 0$. The factorization of $p(\beta)$ (using the value of $B_c$) is given by

$$p(\beta) = -\frac{q(\beta - 1)[\beta(d(q - 1)^2 - (q - 1)) + d(d - q) + q - 1]}{d + 1},$$

which is obviously negative for $\beta > 1$, whenever $d \geq q \geq 2$. \qed

**Proof of Lemma 92.** We compute

$$h'(\beta) = \frac{1}{d}\beta^{-(d - 1)/d} \left[ (q - 1) \left( 1 - \frac{(1 - B_c)(\beta - 1)}{(q - 1)\beta + B_c} \right)^d + B_c \right]$$

$$- d \left[ 1 - \frac{(1 - B_c)(\beta - 1)}{(q - 1)\beta + B_c} \right]^{d - 1} \frac{(1 - B_c)(q - 1 + B_c)[(q - 1)\beta^{1/d} - (q - 2 + B_c)]}{[(q - 1)\beta + B_c]^2}.$$ 

Thus, to prove $h'(\beta) > 0$ it suffices to check (using $q - 1 + B_c = d(1 - B_c)$ and the function $F$ defined in Lemma 91)

$$d^3(1 - B_c)^2 F(\beta)^{(d - 1)/d} \leq \frac{[(q - 1)\beta + B_c]^2}{(q - 1)\beta^{1/d} - (q - 2 + B_c)} \left[ (q - 1) \left( 1 - \frac{(1 - B_c)(\beta - 1)}{(q - 1)\beta + B_c} \right)^d + B_c \right],$$

This is similar to (223) and in fact follows from (223), once we prove that

$$\frac{(q - 1)\beta^{1/d} - (q - 2 + B_c)}{(q - 1)\beta + B_c} \leq \frac{1}{d}.$$ 

To see the last inequality, observe that $\beta + d - 1 \geq d\beta^{1/d}$ as a consequence of the weighted AM-GM inequality (or otherwise). Hence,

$$\frac{(q - 1)\beta^{1/d} - (q - 2 + B_c)}{(q - 1)\beta + B_c} \leq \frac{(q - 1)\beta + (d - 1)(q - 1) - d(q - 2 + B_c)}{d[(q - 1)\beta + B_c]} = \frac{1}{d},$$

completing the proof. \qed
CHAPTER VII

AP REDUCTIONS USING NON-RECONSTRUCTION

For our AP-reductions, we will use a modification of the gadget we analysed in Chapter 4. The properties of the gadget were first proved in the context of the hard-core model in [49].

7.1 A Modified Gadget

Recall from Section 4.1 the definition of the graph distribution $G^r_n$, for integers $n > r \geq 0$:

1. $G^r_n$ is supported on bipartite graphs. The two parts of the bipartite graph are labelled by $+$, $-$ and each is partitioned as $V^s := U^s \cup W^s$ where $|U^s| = n$, $|W^s| = r$ for $s \in \{+, -\}$. $U$ denotes the set $U^+ \cup U^-$ and similarly $W$ denotes the set $W^+ \cup W^-$. 

2. To sample $\tilde{G} \sim G^r_n$, sample uniformly and independently $\Delta$ matchings: (i) $\Delta - 1$ random perfect matchings between $U^+ \cup W^+$ and $U^- \cup W^-$, (ii) a random perfect matching between $U^+$ and $U^-$. The edge set of $G$ is the union of the $\Delta$ matchings. Thus, vertices in $U$ have degree $\Delta$, while vertices in $W$ have degree $\Delta - 1$.

Note here the slight change of notation for a random graph from the distribution $G^r_n$, since we will reserve $G$ for the final gadget. The construction of $G$ has two parameters $0 < \theta, \psi < 1/8$. Let $r = (\Delta - 1)^{[\theta \log \Delta - 1 n] + 2[\frac{\psi}{2} \log \Delta - 1 n]}$, so that $r = o(n^{1/4})$. First, sample $\tilde{G}$ from the distribution $G^r_n$ conditioning on $\tilde{G}$ being simple. Next, for $s \in \{+, -\}$, attach $t$ disjoint $(\Delta - 1)$-ary trees of even depth $\ell$ (with $t = (\Delta - 1)^{[\theta \log \Delta - 1 n]}$ and $\ell = 2[\frac{\psi}{2} \log \Delta - 1 n]$) to $W^s$, so that every vertex in $W^s$ is a leaf of exactly one tree (this is possible since $m' = |W| = t(\Delta - 1)^{\ell}$). Denote by $R^s$ the roots of the trees, so that $|R^s| = t$. The trees do not share common vertices with the graph $G$, apart from the vertices in $W$. The final graph $\tilde{G}$ is the desired gadget.

Note that the definition of the phase of a configuration we gave in Section 4.1 extends to this modified gadget as well. Specifically, the phase of a configuration depends only the spins of vertices $U$ (the large portion of the graph).
The purpose of using the trees in the modified construction is related to Remark 8. The trees, together with (89), will allow to obtain the pointwise conditional independence property 1 for the roots of the trees. The proof will use the non-reconstruction of the Gibbs measures corresponding to dominant phases. To date, the non-reconstruction of these measures has not yet been proved or disproved and thus we do not find appropriate to state and prove a result with the assumption that non-reconstruction holds. Instead, we will content ourselves by showing how this extension can be done in the case of the ferromagnetic Potts model.

7.2 BIS hardness for the Ferromagnetic Potts Model

In this section we prove the BIS hardness results for the ferromagnetic Potts model. Our first objective is to describe the properties of the modified gadget $G$.

The regime which will be interesting to us is $B > B_0$, where Theorem 64 gives the existence of $q$ dominant phases. Recall that the dominant phases for the ferromagnetic Potts model are of the form $(\alpha, \alpha)$, where $\alpha$ ranges over the permutations of $(p', \frac{1-p'}{q-1}, \ldots, \frac{1-p'}{q-1})$, for some $p' > 1/q$. Specifically, $p'$ is the probability that the root of the infinite $\Delta$-regular tree is assigned the spin $i$ in the Gibbs measure corresponding to the ordered phase $i$. More interesting for our considerations in this section will be the same quantity in the $(\Delta - 1)$-ary tree, which we denote by $p$. The probability $p$ is the largest solution bigger than $1/q$ of the following equation

$$
\frac{(q - 1)p}{1 - p} = \left( \frac{(B - 1)p + 1}{(B - 1)\frac{1-p}{q-1} + 1} \right)^{\Delta - 1},
$$

as can easily be derived from the tree recursions (8).

It would be useful to have an explicit form of the product distribution (88). For a phase $i$ and $S \subset V$, we will denote by $Q^i_S(\cdot)$ the product distribution (88) on the set of configurations $\sigma : S \to [q]$. Specifically, for $[i] \in q$ and $\sigma : S \to [q]$, $Q^i_S(\sigma)$ is given by

$$
Q^i_S(\sigma) = p^{\sigma^{-1}(i) \cap S} \left( \frac{1-p}{q-1} \right)^{|R \setminus \sigma^{-1}(i)|},
$$

Our interest in this section will be mostly in the case $S = R$ (the roots of the trees of the gadget), though to analyze the properties of $G$ we will also look at the case $S = W$, in order to transfer our results for the random graph $\tilde{G}$ from Chapter 4.
Using Theorem 31, we prove the following lemma in Section 7.4. The main ingredient here is that the $L^1$ asymptotic convergence of $\mu_G(\sigma_W | Y(\sigma) = i)$ to $Q^i_S(\sigma_W)$ is now an $L^\infty$ asymptotic convergence of $\mu_G(\sigma_R | Y(\sigma) = i)$ to $Q^i_R(\sigma_R)$. Also, due to symmetries of the Potts model, the probability that the phases occur are inverse polynomially close to $1/q$.

**Lemma 93.** For every $\Delta \geq 3$ and $B > \mathcal{B}_o$, there exist constants $\theta(\Delta, B), \psi(\Delta, B) > 0$ such that the graph $G$ satisfies the following with probability $1 - o(1)$ over the choice of the graph:

1. The phases occur with roughly equal probability, so that for every phase $i \in [q]$, we have
   \[
   \left| \mu_G(Y(\sigma) = i) - \frac{1}{q} \right| \leq n^{-2\theta}.
   \]

2. Conditioned on the phase $i$, the spins of vertices in $R$ are approximately independent, that is,
   \[
   \max_{\sigma_R} \left| \frac{\mu_G(\sigma_R | Y = i)}{Q^i_R(\sigma_R)} - 1 \right| \leq n^{-2\theta}.
   \]

With Lemma 93 at hand, we can now give the reduction. Let $B > \mathcal{B}_o$. Let $H$ be a graph on $n'$ vertices, where $n' \leq n^{\theta/4}$ and $\theta$ is as in Lemma 93. Assuming an FPRAS for the ferromagnetic Potts model on max degree $\Delta$ graphs and temperature $B$, we will show that we can approximate $Z_H(B^*)$, the partition function of $H$ in the ferromagnetic Potts model with temperature $B^*$, where $B^*$ will be determined shortly.

To do this, we construct first a graph $H'$. First, take $|H|$ disconnected copies of the gadget $G$ in Lemma 93 and identify each copy with a vertex $v \in H$. Denote by $H^G$ the resulting graph, $G_v$ the copy of the gadget associated to the vertex $v$ in $H$ and by $R_v$ the set of vertices in $R$ in the gadget $G_v$. Second, for each edge $(u,v)$ of $H$, we add an edge between one vertex in $R_u$ and one vertex in $R_v$, using different vertices for distinct edges of $H$. The resulting graph is the graph $H^G$ (note that its maximum degree is $\Delta$). We denote by $R' = \cup_v R_v$.

We have the following connection:
Lemma 94. Let $\Delta \geq 3$ and $B > \mathcal{B}_o$. There exists $B^*$ such that the following holds
\[
(1 - O(n^{-\theta})) \frac{q^m Z_{H^G}(B)}{C_H(Z_G(B))^m} \leq Z_H(B^*) \leq (1 + O(n^{-\theta})) \frac{q^m Z_{H^G}(B)}{C_H(Z_G(B))^m},
\]
where $C_H = D^{|E(H)|}$ and $D = 1 + (B - 1) \left( \frac{2p(1-p)}{(q-1)^2} + (q - 2) \frac{(1-p)^2}{(q-1)^2} \right)$.

Proof of Lemma 94. For each $v \in H$, let $Y_v(\sigma)$ denote the phase of a configuration $\sigma$ on $G_v$ and let $Y = (Y_v)_{v \in H} \in [q]^H$ be the phase vector of vertices in $H$. For $\gamma' \in [q]^H$, let $Z_{H^G}(Y)$ be the partition function of $H^G$ restricted to configurations with phase vector $\gamma'$. That is
\[
Z_{H^G}(\gamma') = \sum_{\gamma : H^G \rightarrow [q]} B^{m(\gamma)} \mathbf{1}\{\gamma(\sigma) = \gamma'\},
\]
where for a configuration $\gamma$, $m(\gamma)$ is the number of monochromatic edges under $\gamma$. We may view $\gamma'$ as an assignment $H \rightarrow [q]$ and analogously we denote by $m(\gamma')$ as the number of monochromatic edges in $H$ under $\gamma'$. We then have
\[
\frac{Z_{H^G}(\gamma')}{Z_{\hat{H}^G}(\gamma')} = \sum_{\gamma_R} \mu_{\hat{H}^G}(\gamma_R | \gamma) \prod_{(u,v) \in E(H^G) \setminus E(\hat{H}^G)} B^{\mathbf{1}\{\gamma(u) = \gamma(v)\}}
\]
Note that $\mu_{\hat{H}^G}(\gamma_R | \gamma) = (1 + O(n^{-\theta})) \prod_{v \in H} Q_{R_v}^{Y_v}(\gamma_R(v))$ since $\hat{H}^G$ is a union of disconnected copies of $G$ and in each copy of $G$ we have property 2. It follows that
\[
\frac{Z_{H^G}(\gamma')}{Z_{\hat{H}^G}(\gamma')} = (1 + O(n^{-\theta})) \sum_{\gamma_R} \prod_{v \in H} Q_{R_v}^{Y_v}(\gamma_R) \prod_{(u,v) \in E(H^G) \setminus E(\hat{H}^G)} B^{\mathbf{1}\{\gamma(u) = \gamma(v)\}}
\]
\[
= (1 + O(n^{-\theta})) A^{m(\gamma')} D^{|E(H)| - m(\gamma')},
\]
where $A$ (resp. $D$) is the expected weight of an edge for two gadgets which have same (resp. different) phases. Simple calculations show that
\[
A = 1 + (B - 1) \left( p^2 + \frac{(1-p)^2}{q-1} \right), \quad D = 1 + (B - 1) \left( \frac{2p(1-p)}{(q-1)^2} + (q - 2) \frac{(1-p)^2}{(q-1)^2} \right).
\]
Letting $B^* = A/D$ and $C_H = D^{|E(H)|}$, we obtain
\[
\frac{Z_{H^G}(\gamma')}{Z_{\hat{H}^G}(\gamma')} = (1 + O(n^{-\theta})) C_H(B^*)^{m(\gamma')}
\]
(224)

Item 1 in Lemma 93 gives that for every $\gamma'$ it holds that
\[
(1 - O(n^{-\theta})) q^{-n'} \leq \left( \frac{1}{q} - n^{-2\theta} \right)^{n'} \leq \frac{Z_{\hat{H}^G}(\gamma')}{Z_{\hat{H}^G}} \leq \left( \frac{1}{q} + n^{-2\theta} \right)^{n'} \leq (1 + O(n^{-\theta})) q^{-n'}. \tag{225}
\]
We also have
\[ Z_{H^G}(B) = \sum_{Y} Z_{H^G}(Y) = \sum_{Y} \frac{Z_{H^G}(Y)}{Z_{H^G}(Y)^*} Z_{H^G}(Y)^* = Z_{H^G} \sum_{Y} \frac{Z_{H^G}(Y)}{Z_{H^G}(Y)^*} = Z_{H^G}. \] (226)

Using the estimates (224), (225) in (226), we obtain
\[ (1 - O(n^{-\theta})) q^{-n'} C_H Z_H (B^*) \leq Z_{H^G}(B) \leq (1 + O(n^{-\theta})) q^{-n'} C_H. \]

The result follows after observing that \( Z_{H^G}(B) = (Z_G(B))^n \) and rearranging the inequality.

\[ \square \]

**Proof of Theorem 16.** Suppose that there exists an FPRAS for approximating the partition function with temperature \( B \) on graphs with maximum degree \( \Delta \). First sample the graph \( G \). \( G \) satisfies the properties in Lemma 93 with probability \( 1 - o(1) \). Approximate the partition function of \( G \) within a multiplicative factor \( 1 \pm \varepsilon/10n' \). Approximate the partition function of \( H^G \) within a multiplicative factor \( 1 \pm \varepsilon/2 \). The bounds for \( Z_H(B^*) \) in Lemma 94 are then within a factor \( 1 \pm \varepsilon \), giving an FPRAS for approximating the partition function with temperature \( B^* \). This, together with the result of [20], implies an FPRAS for counting independent sets in bipartite graphs.

\[ \square \]

### 7.3 BIS hardness for the Hard-Core Model

We first construct the gadget used in the reduction. We start with the same gadget as in the Potts model—except the initial graph will be bipartite (with \( m' \) vertices of degree \( \Delta - 1 \) on each side and \( n \) vertices of degree \( \Delta \) on each side) and we first attach the trees to the vertices on one side and then we attach the trees to the vertices on the other side. Let \( R^+ \) be the roots of the trees attached to one side and let \( R^- \) be the roots of the trees attached to the other side (we use the following shorthands \( R^+ := R^+ \) and \( R^- := R^- \)). As before the final number of vertices on each side is \( k = n^\theta \).

The following lemma captures the properties of the final graph \( G = (V, E) \) (it is similar to Lemma 93, the main difference is that in the first bullet the probabilities of the phases are less balanced—the reason for this is that there is less symmetry between the phases).
Lemma 95. For every $\Delta \geq 3$ and $\lambda > \lambda_c(\Delta)$, for every $\varepsilon > 0$, there exist constants $\theta(\Delta, \lambda), \psi(\Delta, \lambda) > 0$ such that for all sufficiently large $n$ the graph $G$ satisfies with probability $1 - \varepsilon$ the following:

1. The two phases occur with roughly equal probability, so that for every phase $i \in \{\pm 1\}$, we have
   $$\left| \mu_G(Y(\sigma) = i) - \frac{1}{2} \right| \leq \varepsilon.$$

2. Conditioned on the phase $i$, the spins of vertices in $R$ are approximately independent, that is,
   $$\max_{\sigma_R} \left| \frac{\mu_G(\sigma_R | Y = i)}{Q^i(\sigma_R)} - 1 \right| \leq n^{-2\theta},$$
   where $Q^i$ is the following product measure on the configurations $\sigma_R : R^+ \cup R^- \rightarrow \{\pm 1\}$:
   $$Q^i(\sigma_R) = (p^i)_{\sigma_R^{-1}(+1) \cap R^+} | (1 - p^i)_{\sigma_R^{-1}(-1) \cap R^+} | (p^{-i})_{\sigma_R^{-1}(+1) \cap R^-} | (1 - p^{-i})_{\sigma_R^{-1}(-1) \cap R^-},$$
   where $p^j$ is the probability that the root of the infinite $(\Delta - 1)$-ary has spin $+1$ in the ordered phase $j \in \{\pm 1\}$.

Before proceeding with the reduction we will fix some parameters. Let

$$U = 1 - p^+ p^+, \quad W = 1 - p^+ p^-, \quad V = 1 - p^- p^-.$$  \hspace{1cm} (227)

Note that $p^- < p^+$ implies $U < W < V$. We also have

$$W^2 - UV = (p^- - p^+)^2 > 0.$$

Let $0 < a < b$ be such that $a + b = 1$ and

$$U^a V^b = W^{a+b}. \hspace{1cm} (228)$$

Note that for $a = 0, b = 1$ we have $W^{a+b} < U^a V^b$ whereas for $a = b = 1/2$ we have $W^{a+b} > U^a V^b$. Thus such an $a, b$ with $a < b$ exists.

Now we are ready to give the reduction. Let $H$ be a graph with $n'$ vertices. We will need to approximate $a$ and $b$ from the previous paragraph by integers (where the precision
depends on \( H \). By Dirichlet’s theorem on simultaneous Diophantine approximation there exists positive integer \( n'^5 \leq Q \leq n'^{40} \) and integers \( a', b' \in \{0, \ldots, Q\} \) such that

\[
|aQ - a'| \leq n'^{-15} \quad \text{and} \quad |bQ - b'| \leq n'^{-15}.
\]

The gadget from Lemma 95 that we will use will have \( n^\theta \geq n'^80 \). Note that \( n \) is polynomial in \( n' \).

Again, we construct the graph \( H^G \). First, take 2\(|H|\) disconnected copies of the gadget \( G \) from Lemma 95 and identify two copies with a vertex \( v \in H \). Denote by \( \hat{H}^G \) the resulting graph. Let \( G_{v,+1} \) and \( G_{v,-1} \) denote the two copies of the gadget associated to the vertex \( v \) in \( H \). For each \( v \) we put a perfect matching between half of the vertices \( R^+ \) in \( G_{v,+} \) and half of the vertices \( R^+ \) in \( G_{v,-} \), connecting the corresponding vertices. Also, for each \( v \) we put a perfect matching between half of the vertices \( R^- \) in \( G_{v,+} \) and half of the vertices \( R^- \) in \( G_{v,-} \), connecting the corresponding vertices. For each \( v \) call the resulting graph \( G_v \).

Note that \( G_v \) is symmetric—this will deal with the asymmetry in Lemma 95 (intuitively, the only phase assignments that will matter are ones where \( G_{v,+1} \) and \( G_{v,-1} \) have opposite phases—this results in two possibilities and, by symmetry, they have equal probability).

The remaining (unmatched) \( R^- \) vertices from \( G_{v,-1} \) will be referred to as \( L^- \) and the remaining (unmatched) \( R^- \) vertices from \( G_{v,+1} \) will be referred to as \( L^+ \). Let \( \hat{H}^G \) be the union of the \( G_v \)'s.

Now for each edge \( \{u, v\} \) of \( H \) we 1) add matching with \( a' \) edges between the \( L^+ \) vertices of \( G_u \) and \( L^+ \) vertices of \( G_v \) and 2) add a matching with \( b' \) edges between the \( L^- \) vertices of \( G_u \) and the \( L^- \) vertices of \( G_v \).

We have the following connection:

**Lemma 96.** Let \( \Delta \geq 3 \) and \( \lambda > \lambda_c(\Delta) \). The following holds:

\[
(1 - O(n^{-\theta})) \frac{2^{2n'} Z_{HG}(\lambda)}{C_H(Z_G(\lambda))^{2n'}} \leq \text{BIS}(H) \leq (1 + O(n^{-\theta})) \frac{2^{2n'} Z_{HG}(\lambda)}{C_H(Z_G(\lambda))^{2n'}},
\]

where \( C_H = W^{n'k+(a+b)Q|E(H)|} \) and \( W \) is as in (227).

**Proof of Lemma 96.** For each \( v \in H \) and \( i \in \{\pm 1\} \), let \( Y_{v,i}(\sigma) \) denote the phase of a
configuration $\sigma$ on $G_{v,i}$. Let

$$Y_v(\sigma) = \begin{cases} 
-1 & \text{if } Y_{v,+} = +1 \text{ and } Y_{v,-} = -1, \\
+1 & \text{if } Y_{v,+} = -1 \text{ and } Y_{v,-} = +1, \\
0 & \text{otherwise.}
\end{cases}$$

Let $Y = (Y_{v,i})_{v \in H; i \in \{-1, +1\}} \in \{\pm 1\}^{H \times \{-1, +1\}}$ be the phase vector of vertices in $H$ (each vertex gets two phases). For $Y' \in \{\pm 1\}^{H \times \{-1, +1\}}$, let $Z_{HG}(Y')$ be the partition function of $HG$ restricted to configurations with phase vector $Y'$, that is

$$Z_{HG}(Y') = \sum_{\sigma : H \rightarrow \{-1, +1\}} \lambda^{\sum_{\sigma} 1 \{Y(\sigma) = Y\}} \prod_{\{u, v\} \in E(H)} 1 \{\sigma(u) \neq +1 \lor \sigma(v) \neq +1\}.$$

Let $R$ be the union of all $R^+$ and $R^-$ vertices (over all $G_{v,+}$ and $G_{v,-}$) that are matched in the construction. We have

$$\frac{Z_{HG}(Y')}{Z_{HG}(Y')} = \sum_{\sigma_R} \mu_{HG}(\sigma_R | Y(\sigma) = Y') \prod_{\{u, v\} \in E(H)} 1 \{\sigma(u) \neq +1 \lor \sigma(v) \neq +1\},$$

where the sum ranges over all $\sigma_R : R \rightarrow \{\pm 1\}$.

Note that $\mu_{HG}(\sigma_R | Y(\sigma) = Y') = (1 + O(n^{-\theta})) \prod_{v \in H} Q_{R_{v}}(Y_{v})$ since $\hat{H}^G$ is a union of disconnected copies of $G$ and in each copy of $G$ we have property 2. It follows that

$$\frac{Z_{HG}(Y')}{Z_{HG}(Y')} = (1 + O(n^{-\theta})) \prod_{\sigma_R \in H} Q_{R_{v}}(Y_{v}) \prod_{\{u, v\} \in E(H)} 1 \{\sigma(u) \neq +1 \lor \sigma(v) \neq +1\}$$

$$= (1 + O(n^{-\theta})) W^{n'k} \prod_{v \in V(H)} \left(\frac{UV}{W^2}\right)^{(k/2)1 \{Y_{v,+} = Y_{v,-}\}} \prod_{\{u, v\} \in E(H)} F(-Y_{u,+}, -Y_{v,+}) a' F(Y_{u,-}, Y_{v,-}) b',$$

where $F(+, +) = U$, $F(+, -) = W$, and $F(-, -) = V$.

For $Y$ such that $Y_{v,+} = Y_{v,-}$ for some $v$ we have

$$\frac{Z_{HG}(Y')}{Z_{HG}(Y')} \leq (1 + O(n^{-\theta})) W^{n'k} \left(\frac{UV}{W^2}\right)^{(k/2)} V^{(a' + b')|E(H)|}.$$

Assuming $Y_{u,+} \neq Y_{u,-}$ and $Y_{v,+} \neq Y_{v,-}$ (or equivalently $Y_u \neq 0$ and $Y_v \neq 0$) we have

$$\frac{F(-Y_{u,+}, -Y_{v,+}) a' F(Y_{u,-}, Y_{v,-}) b'}{W^{(a+b)Q}} \in \begin{cases} 
[V^{-2n'^{-5/2}}, V^{2n'^{-5/2}}] & \text{if } Y_u \neq +1 \lor Y_v \neq +1, \\
[0, (T^b V^a / W^{a+b})^{n'\alpha}] & \text{if } Y_u = Y_v = +1.
\end{cases}$$

(229)
Hence if $Y_u \neq 0$ and $Y_v \neq 0$ but there exists $\{u, v\} \in H$ such that $Y_u = Y_v = +1$ then
\[
\frac{Z_{HG}(Y')}{\hat{Z}_{HG}(Y')} \leq \left(1 + O(n^{-\theta})\right) W^{n'k + (a+b)Q|E(H)|} \left(U^b V^a \right)^{n'5} V^{(a'+b')|E(H)|}. \tag{231}
\]

On the other hand, if $Y_u \neq 0$ and $Y_v \neq 0$ and for all $\{u, v\} \in H$ we have $Y_u \neq +1 \lor Y_v \neq +1$, then by (230) the edges of $H$ contribute a factor in $[V^{-2n'-1/2}, V^{2n'-1/2}]$. It follows that
\[
\frac{Z_{HG}(Y')}{\hat{Z}_{HG}(Y')} \in \left(1 + O(n^{-\theta})\right) W^{n'k + (a+b)Q|E(H)|}[V^{-2n'-1/2}, V^{2n'-1/2}]. \tag{232}
\]

Item 1 in Lemma 95 gives that for every $Y'$ it holds that
\[
\left(\frac{1}{2} - \varepsilon\right) 2^{n'} \leq \frac{Z_{HG}(Y')}{\hat{Z}_{HG}} \leq \left(\frac{1}{2} + \varepsilon\right) 2^{n'}. \tag{233}
\]

We also have
\[
Z_{HG}(\lambda) = \sum_Y Z_{HG}(Y) = \sum_Y Z_{HG}(Y) Z_{HG}(Y) = Z_{HG} \sum_Y Z_{HG}(Y) Z_{HG}(Y) = \left(\frac{1}{2} + \exp(-\Theta(n^{5}))\right)^{n'}. \tag{234}
\]

Using estimates (229), (230), (231), (232), and (233) we obtain that the contribution of “bad” $Y$ (that is, one with $Y_v = 0$ or with a pair $Y(u) = Y(v) = +1, \{u, v\} \in E(H)$) is $\exp(-\Theta(n^{5}))$ smaller than contribution of “good” $Y$. For good $Y$ we have, by symmetry,
\[
\frac{Z_{HG}(Y)}{\hat{Z}_{HG}} = \left(\frac{1}{2} + \exp(-\Theta(n^{5}))\right)^{n'}. \tag{235}
\]

Now using (232) we obtain the result. \qed

**Proof of Theorem 15.** Suppose that there exists an FPRAS for approximating the partition function with activity $\lambda$ on bipartite graphs of maximum degree $\Delta$. First sample the graph $G$. $G$ satisfies the properties in Lemma 95 with probability $1 - \varepsilon'$, where $\varepsilon'$ can be taken arbitrarily small, say $\varepsilon' = 1/3$. Approximate the partition function of $G$ within a multiplicative factor $1 \pm \varepsilon/10n'$. Approximate the partition function of $HG$ within a multiplicative factor $1 \pm \varepsilon/2$. The bounds for BIS($H$) in Lemma 94 are then within a factor $1 \pm \varepsilon$, giving an FPRAS for counting independent sets in bipartite graphs. \qed

### 7.4 Proving the Properties of the Modified Gadgets

In this section, we prove Lemmas 93 and 95. First, we fix some notation that will be used in the proofs of both lemmas.
We denote by \( J \) the graph induced by the edges in \( G \setminus \bar{G} \) (thus, the vertices in \( W \) belong to \( J \)). Note that \( J \) is the disjoint union of \( 2t \) trees, where \( t = (\Delta - 1)^{\left\lfloor \log_{\Delta - 1} n \right\rfloor} = O(n^\theta) \).

We use \( \sigma_J \) to denote a configuration on the vertices on \( J \) and \( \mu_J(\cdot) \) to denote the Gibbs distribution on \( J \).

We will need to connect the partition function on \( G \) with the partition functions on \( \bar{G} \) and \( J \). The latter two interplay only via the spins of vertices in \( W \). Thus, for a configuration \( \eta : W \to \{q\} \), define \( \Sigma^{i,\eta}_J \) to be the configurations \( \sigma \in \bar{G} \) such that \( Y(\sigma) = i \) and \( \sigma_W = \eta \); \( Z^{i}_G(\eta) \) will denote the total weight of configurations in \( \Sigma^{i,\eta}_J \). Analogously, define \( \Sigma^{J}_J \) to be the configurations \( \sigma \in \bar{G} \) such that \( \sigma_W = \eta \), and \( Z_{J}(\eta) \) the total weight of the configurations in \( \Sigma^{J}_{J} \). Finally, let \( \Sigma^{i}_G \) be the configurations \( \sigma \in G \) such that \( Y(\sigma) = i \), and \( Z^{i}_G \) the total weight of the configurations in \( \Sigma^{i}_G \). With these definitions we have:

\[
Z^{i}_G = \sum_{\eta} Z^{i}_G(\eta) Z_J(\eta), \quad Z_G = \sum_{i} Z^{i}_G, \quad \mu_G(Y(\sigma) = i) = \frac{Z^{i}_G}{Z_G}
\]

Moreover,

\[
\mu_{\bar{G}}(\sigma_W = \eta | Y(\sigma) = i) = \frac{Z^{i}_{\bar{G}}(\eta)}{\sum_{\eta'} Z^{i}_{\bar{G}}(\eta')}, \quad \mu_G(\sigma_W = \eta | Y(\sigma) = i) = \frac{Z^{i}_{\bar{G}}(\eta) Z_{J}(\eta)}{\sum_{\eta'} Z^{i}_{\bar{G}}(\eta') Z_{J}(\eta')}
\]

### 7.4.1 Proof of Lemma 93

The proof follows closely the approach given in [49], suitably adapted. Fix a phase \( i \in \{q\} \).

Remark 8 yields

\[
\left| \sum_{\eta : W \to \{q\}} \left[ \frac{\mu_{\bar{G}}(\sigma_W = \eta | Y(\sigma) = i)}{Q^{i}_W(\eta)} - 1 \right] \right| \leq \frac{\varepsilon}{2}.
\]

Let \( B \) be the set of configurations on \( W \) that cause a “significant influence” on the roots of the trees. Precisely, for a constant \( \zeta_1 > 0 \), let

\[
B := \{ \eta : W \to \{q\} : |\mu_G(\sigma_R | \sigma_W = \eta) - Q^i_R(\sigma_R)| \geq \exp(-\zeta \ell) \}
\]

\[
= \{ \eta : W \to \{q\} : |\mu_J(\sigma_R | \sigma_W = \eta) - Q^i_R(\sigma_R)| \geq \exp(-\zeta_1 \ell) \}.
\]

Recall here that \( \ell \) denotes the height of the trees, i.e., \( \ell = 2^{\left\lfloor \frac{\psi}{2} \log_{\Delta - 1} n \right\rfloor} \). The second equality follows from the Markov property of the Gibbs distribution (conditioned on the configuration on \( W \), the spins on \( R \) are independent of the spins in \( U \)). Since the phase
depends only on $U$, the same token gives

$$
\mu_G(\sigma_R | Y(\sigma) = i) = \mu_G(\sigma_W \in B | Y(\sigma) = i) \mu_G(\sigma_R | \sigma_W \in B) + \mu_G(\sigma_R \notin B | Y(\sigma) = i) \mu_G(\sigma_R | \sigma_W \notin B),
$$

so that

$$\left| \frac{\mu_G(\sigma_R = \eta' | Y(\sigma) = i)}{Q_R(\sigma_R)} - 1 \right| \leq \frac{\mu_G(\sigma_W \in B | Y(\sigma) = i)}{Q_R(\sigma_R)} + \frac{|\mu_G(\sigma_R = \eta' | \sigma_W \notin B) - Q_R^i(\sigma_R)|}{Q_R(\sigma_R)}.
$$

Using the required reconstruction results in [36, Proof of Theorem 1.4] for the ferromagnetic Potts model on the tree with constant boundary condition, we obtain

$$\frac{\mu_G(\sigma_W \in B | Y(\sigma) = i)}{Q_R^i(\sigma_R)} \leq n^{-4\theta},$$

for $\theta$ small enough.

Note that $\min_{\eta'} Q_R^i(\sigma_R = \eta') = \Omega(\exp(n^{-\theta}))$, where the implicit constant depends only on $B, \Delta$. Hence, by the definition of the bad set $B$, for all $0 < \theta < \zeta_1\psi/3$ we have that

$$\left| \frac{\mu_G(\sigma_R = \eta' | \sigma_W \notin B) - Q_R^i(\sigma_R)}{Q_R^i(\sigma_R = \eta')} \right| \leq \exp(n^{-2\theta}).$$

To prove the first item, let $\Sigma_G^i$ be the set of configurations in $G$ which have phase $i$, i.e. $\Sigma_G^i = \{\sigma : V \rightarrow [q] | Y(\sigma) = i\}$. Moreover let $\Sigma_G^0$ be the configurations $\sigma$ with $|\arg \max_{i \in [q]} |\sigma^{-1}(i) \cap U| | \geq 2$, that is, $\Sigma_0$ consists of these configurations whose phase was determined by breaking a tie.

Let $\pi$ be a permutation of the colors $[q]$ which maps color $i$ to color $j$. For a configuration $\sigma$, we denote by $\pi(\sigma)$ the configuration $\pi \circ \sigma$. Clearly, for every configuration $\sigma \in \Sigma_G^i \setminus \Sigma_G^0$, we have $\pi(\sigma) \in \Sigma_G^j \setminus \Sigma_G^0$. It follows that for every two colors $i, j$ we have $Z_G(\Sigma_G^i \setminus \Sigma_0) = Z_G(\Sigma_G^j \setminus \Sigma_G^0)$. Since

$$Z_G = Z_G(\Sigma_G^0) + \sum_i Z_G(\Sigma_G^i \setminus \Sigma_G^0),$$

to get the inequality in Item 1 it suffices to show that $Z_G(\Sigma_G^0)$ is smaller than $Z_G$ by an arbitrary polynomial factor. Define $Z_G^0(\Sigma_G^0)$ analogously to $Z_G(\Sigma_G^0)$. We have that $Z_G^0(\Sigma_G^0)$ is exponentially smaller than $Z_G$. To transfer this to $G$, note that for every configuration on $\overline{G}$, the multiplicative contribution of the configurations on the trees to the partition function is at most $\exp(n^{1/2})$, which gives $Z_G^0(\Sigma_G^0) \leq \exp(n^{1/2})Z_G^0(\Sigma_G^0)$. For large enough $n$ this is at least a polynomial factor smaller than $Z_G$ and hence $Z_G$ as well, as desired.
7.4.2 Proof of Lemma 95

The second item of the lemma is proved in [49], extended in [16] and [17]. The first item in our current version of the lemma has a more delicate bound than in [49], where the more precise bound was not needed. We show how to obtain the desired bound using Remark 8.

Keeping the notation we introduced in the beginning of the section, we have \( E_G[Z^\pm_G(\eta)] = (1 + o(1))E_G[Z^\mp_G(\eta)] \). It is also simple to see that The small graph conditioning method gives that for all sufficiently large \( n \), there exist random variables \( W_{mn} \), a function of the number of cycles of length \( 2, 4, \ldots, 2m \) in \( \tilde{G} \), such that \( Z^i_G(\eta) = (W_{mn} \pm \varepsilon)E_G[Z^i_G(\eta)] \) with probability \( 1 - \varepsilon \). As we saw, when the graph is bipartite, the random variable \( W_{mn} \) is bounded by a constant \( c > 0 \) for all \( m \). Let \( \varepsilon' \) be sufficiently smaller than \( c \). It follows that

\[
|\mu_G(Y(\sigma) = +) - \mu_G(Y(\sigma) = -)| \leq \frac{\varepsilon' \sum_{\eta} Z_J(\eta)}{(c - \varepsilon') \sum_{\eta} Z_J(\eta)} = \frac{\varepsilon'}{c - \varepsilon'}.
\]

This gives the desired result.
In this chapter, we discuss how our results extend to random $\Delta$-regular graphs. We are going to establish that for ferromagnetic models our techniques can be used to completely analyze the Gibbs distribution on a random $\Delta$-regular graph, in a completely analogous way as we did for bipartite graphs. For models which are not ferromagnetic, we will need the extra assumption of semi-translation invariant uniqueness to analyze the Gibbs distribution.

8.1 Preliminaries

8.1.1 The distribution on $\Delta$-regular Graphs

We will use the standard pairing model, introduced in [5] (see also [2]), to study random $\Delta$-regular bipartite graphs.

For $\Delta \geq 3$ and $\Delta n$ even, consider the set $[\Delta n]$. Elements of $[\Delta n]$ will be called points and a pairing of the points is a perfect matching of $[\Delta n]$. The pairing model $G_{n,\Delta}$ is a probability distribution on $\Delta$-regular multigraphs. The distribution is generated by the following random process. First, sample a uniformly random pairing of the points. Given the pairing, construct a graph $G$ with $n$ vertices by identifying for $i = 1, \ldots, n$ the points $\Delta(i - 1) + 1, \ldots, \Delta i$ as a single vertex. The edges of $G$ are induced by the pairing in the natural way.

Let $G \sim G_{n,\Delta}$. $G$ is simple if it does not contain parallel edges or self loops. Every simple graph $G$ corresponds to exactly $(\Delta!)^n$ pairings (note that this is not true if $G$ is not simple). Let $G^s_{n,\Delta}$ denote the conditional distribution on the event that $G$ is simple; it follows that $G^s_{n,\Delta}$ is the uniform distribution over $\Delta$-regular graphs with $n$ vertices. For fixed $\Delta$, the probability that $G$ is simple tends to $\exp\left(-\frac{(\Delta^2 - 1)}{4}\right)$ as $n \to \infty$ ([2, 5]). Consequently, a property holds asymptotically almost surely over the distribution $G_{n,\Delta}$ iff it holds asymptotically almost surely over the distribution $G^s_{n,\Delta}$; the distributions $G_{n,\Delta}$ and $G^s_{n,\Delta}$ are thus contiguous (see [26, Section 9.6] for an account of contiguity).
We will invariably work with the pairing model and translate the results to $G^*_n,\Delta$ per our needs. With a slight abuse of terminology, due to the contiguity of $G_n,\Delta$ and $G^*_n,\Delta$, we shall refer to $G_n,\Delta$ as the distribution of uniformly random $\Delta$-regular graphs; since our results hold a.a.s. over $G_n,\Delta$, this should not lead to any confusions. We will also omit $\Delta$ from notation whenever the context is clear.

8.1.2 Ferromagnetic Spin Systems

Before giving the definition of a ferromagnetic spin system in terms of the interaction matrix $B$, we note that there is no loss of generality to assume in this chapter that $B$ is ergodic (irreducible and aperiodic), as a consequence of the fact that a random $\Delta$-regular graph is almost surely connected and non-bipartite. Indeed, if $B$ is reducible by a suitable permutation of the labels of colors, $B$ can be put in a block diagonal form where each of the blocks is either irreducible or zero. The original spin system can be studied by considering the induced sub-models of each block which correspond to irreducible symmetric matrices (where our results apply). These sub-models are “non-interacting” for connected graphs $G$, that is, the partition function for the original model is simply the sum of the partition functions of each sub-model. Similarly, if $B$ is periodic, its period must be two since $B$ is symmetric; such a model is only interesting on bipartite graphs.

To define ferromagnetic systems, recall that in Section 5.1 we defined antiferromagnetic spin systems as those spin systems whose interaction matrix $B$ has a single positive eigenvalue and the rest are negative. Analogously, we use the following definition of ferromagnetic spin systems.

**Definition 7.** A model is called **ferromagnetic** if $B$ is positive definite. Equivalently we have that all of its eigenvalues are positive and also that

$$B = \hat{B}^\top \hat{B}, \quad \text{(15)}$$

for some $q \times q$ matrix $\hat{B}$.

The most alluring aspect of this definition is that for a ferromagnetic model, neighboring vertices prefer to have the same spin. More generally, and analogously to Lemma 52, we
have the following simple application of the Cauchy-Schwarz inequality.

**Lemma 97.** Let $\mathbf{z}_1, \mathbf{z}_2 \in \mathbb{R}^q_{\geq 0}$ with $\|\mathbf{z}_1\|_1 = \|\mathbf{z}_2\|_1 = 1$. For ferromagnetic $\mathbf{B}$, we have

$$ (\mathbf{z}_1^\top \mathbf{B} \mathbf{z}_1)(\mathbf{z}_2^\top \mathbf{B} \mathbf{z}_2) \geq (\mathbf{z}_1^\top \mathbf{B} \mathbf{z}_2)^2. \quad (236) $$

Equality holds iff $\mathbf{z}_1 = \mathbf{z}_2$. Recall that for antiferromagnetic $\mathbf{B}$, the inequality is reversed.

Observe that if we plug in the inequality (236) the vectors with a single 1 in the positions $i$ and $j$ respectively, we obtain that any two spins $i, j$ induce a ferromagnetic two-spin system.

**Proof of Lemma 97.** Just use the decomposition (15) and use the Cauchy-Scharz inequality on the vectors $\hat{\mathbf{B}} \mathbf{z}_1$ and $\hat{\mathbf{B}} \mathbf{z}_2$. \qed

We also remind the reader that the definition of ferromagnetism/antiferromagnetism in terms of the signature of the interaction matrix is invariant in the presence of external fields. In particular, for $\Delta$-regular graphs, any external field can be pushed into the interaction matrix $\mathbf{B}$ with a congruence transformation of the matrix $\mathbf{B}$. The resulting interaction matrix, by Sylvester’s law of inertia, has the same number of positive, zero and negative eigenvalues and in particular remains ferromagnetic/antiferromagnetic.

### 8.1.3 First and Second Moments

For a $q$-spin system with interaction matrix $\mathbf{B}$, our goal is to understand the Gibbs distribution on a random $\Delta$-regular graph $G = (V, E)$ by looking at the distribution of spin values in $V$. Let $n = |V|$. For a configuration $\sigma : V \to [q]$, we denote the set of vertices assigned spin $i$ by $\sigma^{-1}(i)$. For a $q$-dimensional probability vector $\mathbf{\alpha}$, let

$$ \Sigma^\mathbf{\alpha} = \{ \sigma : V \to \{1, \ldots, q\} \mid |\sigma^{-1}(i)| = \alpha_i n \text{ for } i = 1, \ldots, q \}, $$

that is, configurations in $\Sigma^\mathbf{\alpha}$ assign $\alpha_i n$ vertices the spin $i$. We will be interested in the total weight $Z_G^\mathbf{\alpha}$ of configurations in $\Sigma^\mathbf{\alpha}$, namely

$$ Z_G^\mathbf{\alpha} = \sum_{\sigma \in \Sigma^\mathbf{\alpha}} w_G(\sigma). $$
We study $Z_\alpha^G$ by looking at the moments $E_G[Z_\alpha^G]$ and $E_G[(Z_\alpha^G)^2]$, where the expectation is over the distribution of the random $\Delta$-regular bipartite graph, from hereon denoted by $G$.

Denote the leading term of the first and second moments as:

$$
\Psi_1(\alpha) = \Psi_1^B(\alpha) := \lim_{n \to \infty} \frac{1}{n} \log E_G[Z_\alpha^G].
$$

$$
\Psi_2(\alpha) = \Psi_2^B(\alpha) := \lim_{n \to \infty} \frac{1}{n} \log E_G[(Z_\alpha^G)^2].
$$

8.2 Results for General Spin Systems
8.2.1 Reformulating the First Moment

We state an analog of Theorem 5 for the class of random $\Delta$-regular graphs. For random $\Delta$-regular graphs, we will need the (depth one) tree recursions:

$$
\tilde{R}_i \propto \left( \sum_{j=1}^{q} B_{ij} R_j \right)^{\Delta-1}.
$$

(7)

The fixpoints of the tree recursions are those $r = (R_1, \ldots, R_q)$ such that: $\tilde{R}_i \propto R_i$ for all $i \in [q]$. We refer to a fixpoint $r$ of the tree recursions as Jacobian attractive if the Jacobian at $r$ has spectral radius less than 1.

It will also be useful to reformulate the function $\Psi_1$ into the function $\Phi_1$, as we did for random bipartite graphs. The function $\Phi_1$ for random regular graphs takes the form

$$
\Phi_1(r) = \frac{\Delta}{2} \ln \left( \sum_{i=1}^{q} \sum_{j=1}^{q} B_{ij} R_i R_j \right) - (\Delta - 1) \ln \left( \sum_{i=1}^{q} R_i^{\Delta/(\Delta-1)} \right),
$$

(238)

where $r = (R_1, \ldots, R_q)^T \geq 0$. Let $p := \Delta/(\Delta - 1)$. Note that (238) has the following appealing form

$$
\exp(2\Phi_1(r)/\Delta) = \frac{r^T Br}{\|r\|_p^p},
$$

(239)

where $\|r\|_p = (\sum_{i=1}^{n} R_i^p)^{1/p}$.

Lemma 98. There is a one-to-one correspondence between the fixpoints of the depth-one tree recursions and the critical points of $\Phi_1$ (both considered for $R_i \geq 0$ in the projective space, that is, up to scaling by a constant). The following transformation $r \mapsto \alpha$ given by:

$$
\alpha_i = R_i^{\Delta/(\Delta-1)}/\sum_i R_i^{\Delta/(\Delta-1)}
$$

(240)
yields a one-to-one-to-one correspondence between the critical points of $\Phi_1(r)$ and the critical points of $\Psi_1(\alpha)$ (in the region defined by $\alpha_i \geq 0$ and $\sum_i \alpha_i = 1$). Moreover, for the corresponding critical points $r$ and $\alpha$ one has

$$\Phi_1(r) = \Psi_1(\alpha).$$ (241)

Finally, the local maxima of $\Phi_1$ and $\Psi_1$ happen at the critical points (that is, there are no local maxima on the boundary).

The proof of Lemma 98 follows the same arguments as the proof of Theorem 5 in Section 3.2 with $C_j$ identified with $R_j$ and $\beta_j$ identified with $\alpha_j$ and is therefore omitted.

### 8.2.2 Second Moment Analysis in the Semi-Translation Invariant Uniqueness Regime

For general models on random regular graphs, we will be able to analyze the second moment in the semi-translation invariant uniqueness regime, i.e., when the system of equations

$$R_i \propto \left( \sum_{j=1}^q B_{ij} C_j \right)^{\Delta - 1}, \quad C_j \propto \left( \sum_{j=1}^q B_{ij} R_i \right)^{\Delta - 1}$$ (8)

has a unique positive solution (up to scaling the values of the $R_i$’s and $C_j$’s). In particular, this implies (trivially) that the depth-one tree recursions (7) have a unique fixed point. By Lemma 98, we have that the maximizer of the function $\Psi_1(\alpha)$ is unique, i.e., there is unique dominant phase $\alpha^*$.

We prove the following lemma.

**Lemma 99.** Suppose that $B$ specifies a model in the semi-translation invariant uniqueness regime. Then for the unique dominant phase $\alpha^*$, it holds that $\Psi_2(\alpha^*) = 2\Psi_1(\alpha^*)$.

**Proof.** We first show that $\exp(2\Psi_1(\alpha^*)/\Delta) = \|B\|_{\rho \to \Delta}$. From (239) and (12), we obtain:

$$\max_{\alpha} \exp(2\Psi_1(\alpha)/\Delta) = \max_r \frac{r^T Br}{\|r\|_p^2} \leq \max_{r,c} \frac{r^T B c}{\|r\|_p \|c\|_p}. \quad (242)$$

Note that the last inequality is trivial; we just enlarged the region we consider. By Theorem 5, the maximum of the rhs is achieved at a semi-translation invariant fixpoint. Since $B$ specifies a model in the semi-translation invariant uniqueness regime, this must coincide
with the translation invariant fixpoint and hence the maximum in the rhs of (242) must occur at \( r = c \). We thus obtain that (242) is satisfied at equality. On the other hand, the rhs in (242) is equal to \( \|B\|_{p \to \Delta} \), while the lhs is \( \exp(2\Psi_1(\alpha^*)/\Delta) \), thus proving the desired claim.

Using that the second moment corresponds to a spin model with interaction matrix \( B \otimes B \), by the same token, one has the bounds

\[
\Psi_2(\alpha^*) \leq \max_{\alpha \in \Delta_q} \exp(\Psi_2(\alpha)/\Delta) \leq \max_{\alpha \in \Delta_q^2} \exp(\Psi_1(B \otimes B)(\alpha)/\Delta) \leq \|B \otimes B\|_{p \to \Delta},
\]

(243)

Note that from \( E[X^2] \geq (E[X])^2 \), we have (trivially) \( \Psi_2(\alpha^*) \geq 2\Psi_1(\alpha^*) \). Since \( \|B \otimes B\|_{p \to \Delta} = \|B\|^2_{p \to \Delta} \) ([3, Proposition 10.3]), we obtain that (243) holds at equality. This implies \( \Psi_2(\alpha^*) = 2\Psi_1(\alpha^*) \), as wanted.

For the remainder of this section, to lighten notation, we will drop the asterisk to denote the unique dominant phase and set \( \alpha := \alpha^* \). Using the small graph conditioning method and Lemma 99, we can conclude that

\[
Z_G > \frac{1}{n} \exp(n\Psi_1(\alpha)),
\]

(244)

with probability \( 1 - o(1) \) over the choice of \( G \sim \mathcal{G}_{n, \Delta} \). To get (244), we need two extra assumptions: the first is that the matrix \( B \) is regular to utilize the results of Section 3.3.3; the second is that the (unique) translation invariant fixpoint corresponding to \( \alpha \) is Jacobian attractive to infer the negative definiteness of the Hessian, which we need for the calculation of the moments.

Using (244), it is simple to verify the so-called Bethe prediction for random \( \Delta \)-regular graphs in semi-translation invariant uniqueness regimes. We recall here the statement of the relevant theorem from the Introduction.

**Theorem 9.** Let \( B \) be the interaction matrix of a spin system such that \( Z_G > 0 \) for all \( \Delta \)-regular graphs. Assume that there exists a unique semi-translation invariant Gibbs measure on \( T_\Delta \) and the corresponding fixpoint of the tree recurrences (7) is Jacobian attractive. Provided that the matrix \( B \) is regular (non-zero determinant),

\[
\lim_{n \to \infty} \frac{1}{n} E_G[\log Z_G] = \lim_{n \to \infty} \frac{1}{n} \log E_G[Z_G].
\]

(16)
Proof of Theorem 9. Using (244), we obtain

$$\liminf_{n \to \infty} \frac{1}{n} E_G[\log Z_G] \geq \liminf_{n \to \infty} (1 - o(1))\Psi_1(\alpha) + o(1)C = \Psi_1(\alpha),$$

where $C$ is a uniform lower bound on $\log Z_G$ (note that such a bound exists by the assumption $Z_G > 0$ of Theorem 9). Finally, by a standard application of Jensen’s inequality, we have

$$\limsup_{n \to \infty} \frac{1}{n} E_G[\log Z_G] \leq \lim_{n \to \infty} \frac{1}{n} \log E_G[Z_G] = \Psi_1(\alpha),$$

concluding the proof.

We conclude this section by noting that for natural models such as the hard-core or the $k$-colorings model, the second moment has been analyzed even in non-uniqueness regimes. Needless to say that Lemma (244) and Theorem 9 do not improve on these results; the scope of Lemma (244) and Theorem 9 is to provide a simple criterion (uniqueness of semi-translation invariant measures) which applies for fairly general spin systems.

8.3 Results for Ferromagnetic Models

For ferromagnetic models on random regular graphs, we will use the Cholesky decomposition of the interaction matrix $B$ to obtain a matrix norm formulation of the first moment. This will allow us to obtain the following analogue of Theorem 4, which we prove in Section 8.3.1. We restate the relevant theorems.

Theorem 8. For a ferromagnetic model,

$$\max_\alpha \Psi_2(\alpha) = 2 \max_\alpha \Psi_1(\alpha).$$

Specifically, for dominant phases $\alpha$, $\Psi_2(\alpha) = 2\Psi_1(\alpha)$.

We will also obtain the following analogue of Theorem 2 in Section 8.3.2.

Theorem 7. For a ferromagnetic model, Jacobian attractive fixpoints of the (depth one) tree recursions are in one-to-one correspondence with the Hessian local maxima of $\Psi_1$.

The above connection fails for antiferromagnetic models, e.g., for the antiferromagnetic Potts model the uniform distribution is a global maximum but it is not a stable fixpoint.
of the tree recursions for small enough temperature. (In fact, for antiferromagnetic models every solution of the depth one tree recursions is a local maximum, see Remark 12.)

8.3.1 Second Moment Analysis

Since we assume that $B$ is ferromagnetic we have $B = \hat{B}^T \hat{B}$ and hence we can write

$$\exp(\Phi_1(r)/\Delta) = \frac{\|\hat{B}r\|_2}{\|r\|_p},$$  \hspace{1cm} (245)

where $\Phi_1$ was defined in (238). The next lemma describes the connection between $\Phi_1$ and $\Psi_1$. We note that $\Phi_1$ is not a reparameterization of $\Psi_1$, however they do agree at the critical points. This is sufficient for our purpose: to understand the maxima of $\Psi_1$ it is enough to understand the maxima of $\Phi_1$. The maximization

$$\max_{r \geq 0} \|\hat{B}r\|_2 = \max_{r} \|\hat{B}r\|_p = \|B\|_{p \to 2},$$  \hspace{1cm} (246)

is the induced $p \to 2$ matrix norm of $\hat{B}$. The first equality in (246) follows from the fact that the maximum on the right-hand-side of (239) is achieved for non-negative $r$ (this follows from the fact that $B$ has non-negative entries).

Lemma 5 allows us to reexpress the optimization problem associated with the first moment in terms of matrix norms.

**Lemma 100.** Let $B$ be the interaction matrix of a ferromagnetic spin system. We have

$$\max_{\alpha} \Psi_1(\alpha) = \Delta \ln \|\hat{B}\|_{\Delta \to 2 \to 2}.$$

**Proof.** Using Lemma 5 and equations (245) and (246), we obtain

$$\max_{\alpha} \exp(\Psi_1(\alpha)/\Delta) = \max_{r} \exp(\Phi_1(r)/\Delta) = \|\hat{B}\|_{p \to 2}.$$

Recall, the definition of $\Psi_2$ (see (237)) corresponding to the leading term of the second moment. A key fact is that $\Psi_2$ is given by a constrained first moment calculation on a “paired-spin” model where the interaction matrix in this model is the tensor product of the original interaction matrix with itself (see Remark 14 in Section 8.4). The second moment
considers a pair of configurations, say \( \sigma \) and \( \sigma' \), which are constrained to have a given phase \( \alpha \). We capture this constraint using a vector \( \gamma \) corresponding to the overlap between \( \sigma \) and \( \sigma' \), in particular, \( \gamma_{ij} \) is the number of vertices with spin \( i \) in \( \sigma \) and spin \( j \) in \( \sigma' \).

Recall, \( \Psi_1^B \) indicates the dependence of the function \( \Psi_1 \) on the interaction matrix \( B \); to simplify the notation we will drop the exponent if it is \( B \). More precisely,

\[
\Psi_2(\alpha) = \max_{\gamma} \Psi_1^{B \otimes B}(\gamma),
\]

where the optimization in (247) is constrained to \( \gamma \) such that

\[
\sum_i \gamma_{ik} = \alpha_k \quad \text{and} \quad \sum_k \gamma_{ik} = \alpha_i.
\]

Ignoring the two constraints in (248) can only increase the value of (247) and hence

\[
\max_{\alpha} \exp(\Psi_2(\alpha)/\Delta) \leq \max_{\gamma} \exp(\Psi_1^{B \otimes B}(\gamma)/\Delta) = \| \hat{B} \otimes \hat{B} \|_{\Delta \rightarrow \Delta-1}^2. \tag{249}
\]

For induced norms \( \| \cdot \|_{p \rightarrow q'} \) with \( p \leq q' \) it is known (Proposition 10.1 in [3]) that

\[
\| \hat{B} \otimes \hat{B} \|_{p \rightarrow q'} = \| \hat{B} \|_{p \rightarrow q'} \| \hat{B} \|_{p \rightarrow q'}. \tag{250}
\]

Now we are ready to prove Theorem 8.

**Proof of Theorem 8.** Combining Lemma 100 and equations (249),(250) we obtain:

\[
\exp(\Psi_2(\alpha)/\Delta) = \max_{\gamma} \exp(\Psi_1^{B \otimes B}(\gamma)/\Delta) \leq \| \hat{B} \otimes \hat{B} \|_{\Delta \rightarrow \Delta-1}^2 = 2 \max_{\alpha} \exp(\Psi_1(\alpha)/\Delta).
\]

This proves that if \( \alpha \) maximizes \( \Psi_1 \), we have \( \Psi_2(\alpha) \leq 2\Psi_1(\alpha) \). The reverse inequality is trivial, yielding Theorem 8. \( \Box \)

**Remark 11.** We will illustrate the necessity of the ferromagnetism assumption in Theorem 8 by giving an example of an antiferromagnetic model for which the second moment fails. Consider proper 3-colorings of random 10-regular graphs. As the size of the graph goes to infinity the probability of it being 3 colorable goes to zero. The intuitive effect of this is that to achieve a large value in the “paired-spin” model it is better to correlate the coordinates to agree. In terms of \( \Psi_1 \) and \( \Psi_2 \) we have that the maximum in the first moment is achieved for \( \alpha_1 = \alpha_2 = \alpha_3 = 1/3 \) with \( \Psi_1 = 5 \ln 2 - 4 \ln 3 < 0 \). To obtain a lower
bound on the maximum in the second moment we take $\gamma_{11} = \gamma_{22} = \gamma_{33} = 1/3$, which yields $\Psi_2 = \Psi_1 > 2\Psi_1$. The argument actually applies whenever $\Psi_1 < 0$ (for models whose interaction matrices have 0’s and 1’s). By continuity (taking small $B$ in antiferromagnetic Potts model) one can obtain an example of a model without hard constraints for which the second moment fails.

8.3.2 Jacobian Stability and Hessian Maxima

The proof of Theorem 7 is essentially identical to that of Theorem 2 after identifying $C_j$’s with $R_j$’s and $\beta_j$’s with $\alpha_j$’s. Here, we give an overview of the proof including the important formulas.

Our starting point is the one-to-one correspondence between fixpoints of the tree recursions and the critical points of $\Psi_1$, as given in Lemma 98. We show, roughly, that the stability of a fixpoint is equivalent to the local maximality of the corresponding critical point. This will be done by relating the Jacobian of the tree recursions at a fixpoint with the Hessian of $\Psi_1$ at the corresponding critical point. More precisely, we show that the Jacobian has spectral radius less than 1 (a sufficient condition for stability) if and only in the Hessian is negative definite (a sufficient condition for local maximality). Both constraints on the matrices are independent of the choice of local coordinates (that is, they are invariant under similarity transformations), however to make the connection between the Jacobian and the Hessian apparent we will have to choose the local coordinates very carefully. A further technical complication is that the tree recursions are in the projective space and that the optimization of $\Psi_1$ is constrained.

We give a high level overview of the Jacobian; the proofs for the $\Delta$-regular case follow the same reasoning as for the bipartite $\Delta$-regular case, see [18, Section E.2], after simply changing $C_j$’s to $R_j$’s and $\beta_j$’s to $\alpha_j$’s. Assume that $R_1, \ldots, R_q$ is a fixpoint of the tree recursions. Now we consider an infinitesimal perturbation of the fixpoint $R_1 + \varepsilon R_1', \ldots, R_q + \varepsilon R_q'$ and see how it is mapped by the tree recursions. Let $\alpha_i := \sum_j B_{ij}R_iR_j$. The right parametrization (choice of local coordinates) is to take $R_i' = r_iR_i/\sqrt{\alpha_i}$, where $r_1, \ldots, r_q$ determines the perturbation. Note that $R_i/\sqrt{\alpha_i}$ depends on the fixpoint. The tree recursions
map (in the projective space) the perturbation as follows:

\[
\left( R_1 + \varepsilon r_1 R_1, \ldots, R_q + \varepsilon r_q R_q \right) \mapsto \left( R_1 + \varepsilon \hat{r}_1 R_1, \ldots, R_q + \varepsilon \hat{r}_q R_q \right) + O(\varepsilon^2),
\]  

(251)

where \( \hat{r}_i \)'s are given by the following linear transformation

\[
\hat{r}_i = (\Delta - 1) \sum_{j=1}^{q} B_{ij} R_i R_j \sqrt{\alpha_i \alpha_j} r_j,
\]  

(252)

and where the \( r_i \)'s are required to satisfy

\[
\sum_{i=1}^{q} \sqrt{\alpha_i} r_i = 0.
\]  

(253)

The condition (253) is invariant under the map (252) and corresponds to choosing the representative of \( R_1, \ldots, R_q \) with \( \sum_i \sum_j B_{ij} R_i R_j = 1 \).

Next we give a high level description of the Hessian; again, this is almost identical to the one in [18, Section E.1] after identifying \( C_j \)'s with \( R_j \)'s and \( \beta_j \)'s with \( \alpha_j \)'s. Recall that \( \Psi_1 \) is a function of \( \alpha_1, \ldots, \alpha_q \). There is an alternative parameterization of \( \Psi_1 \): instead of \( \alpha_1, \ldots, \alpha_q \) (restricted to \( \sum \alpha_i = 1 \)) we use \( R_1, \ldots, R_q \) (restricted to \( \sum \sum B_{ij} R_i R_j = 1 \)) and use the following

\[
\alpha_i = \sum_j B_{ij} R_i R_j \quad \text{for all } i \in [q].
\]  

(254)

Every \( \alpha \) can be achieved using parameterization by \( R \). Let \( \alpha_1, \ldots, \alpha_q \) be a critical point of \( \Psi_1 \) and let \( R_1, \ldots, R_q \) satisfy (254). We are going to evaluate \( \Psi_1 \) in a small neighborhood around \( \alpha_1, \ldots, \alpha_q \). It is equivalent (and easier to understand) to perturb the \( R_1, \ldots, R_q \) to \( R_1 + \varepsilon R_1', \ldots, R_q + \varepsilon R_q' \) and evaluate at the point given by (254). Again, the correct parameterization is to take \( R_i' = r_i R_i / \sqrt{\alpha_i} \). This yields the following expression for the value of \( \Psi_1 \) at the perturbed point

\[
\Psi_1(\alpha_1, \ldots, \alpha_q) + \varepsilon^2 \sum_{i=1}^{q} \left( r_i + \sum_{j=1}^{q} B_{ij} R_i R_j \sqrt{\alpha_i \alpha_j} r_j \right) \left( \sum_{j=1}^{q} (\Delta - 1) \frac{B_{ij} R_i R_j}{\sqrt{\alpha_i \alpha_j}} r_j - r_i \right) + O(\varepsilon^3).
\]  

(255)

Note that there is no linear term, since we are at a critical point. Recall that the \( \alpha_i \) have to satisfy \( \sum \alpha_i = 1 \) which corresponds to the restriction (253).

Now we are ready to prove Theorem 2. Let \( L \) be a linear map such that the Jacobian (252) is \((\Delta - 1)L\). The Hessian of \( \Psi_1 \) is then \((I + L)((\Delta - 1)L - I)\). Finally let \( S \) be the linear subspace defined by (253).
Proof of Theorem 2. The constraint for the fixpoint to be Jacobian attractive is that \((\Delta - 1)L\) on \(S\) has spectral radius less than 1, see equation (251). The constraint for the critical point to be Hessian maximum is that the eigenvalues of \((I + L)((\Delta - 1)L - I)\) on \(S\) are negative, see equation (255).

Note that \(L\) is symmetric and if \(B\) is positive semidefinite then \(L\) is positive semidefinite (since \(L\) is congruent to \(B\); \(L\) is obtained by multiplying \(B\) by a diagonal matrix on the left and on the right). Hence \(L\) has non-negative real spectrum. Note that \(S\) is invariant under \(L\) and hence the spectrum of \(L\) on \(S\) is a subset of the spectrum of \(L\) (it is still non-negative real; the restriction wiped out the eigenvalue 1).

The constraint for the fixpoint to be Jacobian attractive, in terms of eigenvalues, is: for each eigenvalue \(x\) of \(L\) on \(S\)
\[
(\Delta - 1)|x| < 1.
\]

The constraint for the critical point to be Hessian maximum, in terms of eigenvalues, is: for each eigenvalue \(x\) of \(L\) on \(S\)
\[
(1 + x)((\Delta - 1)x - 1) < 0.
\]

Note that conditions (256) and (257) are equivalent (since \(x \geq 0\)).

Remark 12. For antiferromagnetic models every critical point of \(\Psi_1\) is a local maximum. Indeed, we need only to prove that equation (257) is satisfied for every critical point. The matrix \(L\) has non-negative entries hence 1 is the largest eigenvalue and all the other eigenvalues have magnitude less than 1 (since \(B\) is ergodic). Moreover the matrix \(L\) has the same signature as \(B\) (since they are congruent) and hence the eigenvalues other than 1 are negative. These 2 facts imply (257).

Remark 13. Note that one direction of the implication in Theorem 2, namely, that a Jacobian attractive fixpoint is Hessian local maximum, holds for every model (without the ferromagnetism assumption), since (256) always implies (257). However, for the reverse implication, the ferromagnetic assumption is essential. For example, in an antiferromagnetic model, by Remark 12, every critical point is a local maximum. For the antiferromagnetic
Potts model, the only critical point is the uniform vector and hence it is always a local maximum for every value of $B$. On the other hand, it is straightforward to check that for the antiferromagnetic Potts model the uniform fixpoint is Jacobian unstable when $B < \frac{\Delta - q}{\Delta}$.

### 8.4 Expressions for $\Psi_1$ and $\Psi_2$

In this section, we derive expressions for the first and second moments of $Z^\alpha_G$, which will allow us to derive explicit expressions for the functions $\Psi_1(\alpha)$ and $\Psi_2(\alpha)$. Our exposition here is such that it provides a straightforward alignment with the analogous expressions in Chapter 2. The minor differences are due to the model of $\Delta$-regular random graphs, which in this chapter is the pairing model $G := G_{n,\Delta}$ defined in Section 2.1.1.

Recall, $\Delta_t$ denotes the simplex

$$\Delta_t = \{(x_1, x_2, \ldots, x_t) \in \mathbb{R}^t \mid \sum_{i=1}^t x_i = 1 \text{ and } x_i \geq 0 \text{ for } i = 1, \ldots, t\}.$$  (258)

Let $G \sim G$. For a configuration $\sigma : V \to \{1, \ldots, q\}$, we shall denote the set of vertices assigned color $i$ by $c_i(\sigma)$. For $\alpha \in \triangle_q$ and $n\alpha \in \mathbb{Z}^q$, let

$$\Sigma^\alpha = \{\sigma : V \to \{1, \ldots, q\} \mid |c_i(\sigma)| = \alpha_i n, \text{ for } i = 1, \ldots, q\},$$

that is, $\Sigma^\alpha$ is the set of configurations $\sigma$ which assign $\alpha_i n$ vertices of $V$ the color $i$, for each $i \in [q]$. We are interested in the total weight $Z^\alpha_G$ of configurations in $\Sigma^\alpha$, namely

$$Z^\alpha_G = \sum_{\sigma \in \Sigma^\alpha} w_G(\sigma).$$

Note that $Z^\alpha_G$ is a r.v., and as indicated earlier, we will look at its moments $\mathbb{E}_G[Z^\alpha_G]$ and $\mathbb{E}_G[(Z^\alpha_G)^2]$.

We begin with the first moment. For $\sigma \in \Sigma^\alpha$ and $i, j \in [q]$, let $e_{ij} n$ denote the number of edges matching vertices in $c_i(\sigma)$ and $c_j(\sigma)$. Clearly, $e_{ij} = e_{ji}$. It will be notationally convenient to reparameterize the variables $e_{ij}$ as follows: for $i \neq j$ we set $e_{ij} = \Delta_x e_{ij}$ and for $i = j$ we set $e_{ii} = \Delta_x e_{ii}/2$. Note that the $x_{ij}$ are r.v., since they depend on the choice of the random graph $G$. For future use, we denote by $x_G(\sigma)$ the random vector $(x_{11}, \ldots, x_{qq})$.

The number of perfect matchings between $2n$ vertices will be denoted by $(2n)!!$. It is well known and easy to see that $(2n)!! = (2n)!/(n!2^n)$. Under the convention that $0^0 \equiv 1$,
we then have
\[
\mathbb{E}_G[Z^\alpha_G] = \left(\begin{array}{c} n \\ \alpha_1, \ldots, \alpha_q \end{array}\right)
\sum_x \prod_i \left( \frac{\Delta\alpha_i n}{\Delta x_i n, \ldots, \Delta x_{iq} n} \right) \left[ \prod_{i 
eq j} \frac{(\Delta x_{ij} n)!}{(\Delta n)!} \prod_i (\Delta x_{ii} n)!! \right]^{1/2} \prod_{i,j} B_{ij}^{\Delta x_{ij} n/2},
\]
(259)
where the sum ranges over all the possible values of the random vector \( x_G(\sigma) \), that is, \( x = (x_{11}, \ldots, x_{qq}) \) satisfying:
\[
\sum_j x_{ij} = \alpha_i \quad (\forall i \in [q]),
\]
\[
x_{ij} = x_{ji} \geq 0 \quad (\forall i, j \in [q]).
\]
(260)
The first line in (259) accounts for the cardinality of \( \Sigma^\alpha \), while the second line is \( \mathbb{E}_G[w_G(\sigma)] \) for a fixed \( \sigma \in \Sigma^\alpha \), since by symmetry we may focus on any fixed \( \sigma \). The first product is the number of ways to choose a partition of the points which is consistent with the values prescribed by \( x \), the fraction is the probability that the random matching connects the points as prescribed, and the last product is the weight of the configuration \( \sigma \) conditioned on \( x \).

We next deal with the second moment of \( Z^\alpha_G \). The desired expression may be derived analogously to (22). For \((\sigma_1, \sigma_2) \in \Sigma^\alpha \times \Sigma^\alpha \), we need to compute \( \mathbb{E}_G[w_G(\sigma_1)w_G(\sigma_2)] \). For \( i, k \in [q] \), let \( \gamma_{ik} n = |c_i(\sigma_1) \cap c_k(\sigma_2)| \). The vector \( \gamma \) captures the overlap of the configurations \( \sigma_1, \sigma_2 \). Denote by \( e_{ikjl} n \) the number of edges matching vertices in \( c_i(\sigma_1) \cap c_k(\sigma_2) \) and \( c_j(\sigma_1) \cap c_l(\sigma_2) \). We reparameterize as follows: for \((i, k) \neq (j, l)\) we set \( e_{ikjl} = \Delta y_{ikjl} \) and for \((i, k) = (j, l)\) we set \( e_{ikjl} = \Delta y_{ikjl}/2 \).

\[
\mathbb{E}_G[(Z^\alpha_G)^2] = \sum_{\gamma} \binom{n}{\gamma_{11} n, \ldots, \gamma_{qq} n}
\sum_y \prod_{i,k} \left( \Delta y_{ik11} n, \ldots, \Delta y_{ikqq} n \right) \left[ \prod_{(i,j) \neq (k,l)} (\Delta y_{ikjl} n)! \right]^{1/2} \prod_{i,k} (\Delta y_{ikik} n)!! \prod_{i,j} (B_{ij} B_{kl}) \Delta y_{ikjl} n/2,
\]
(261)
where the sums range over \( \gamma = (\gamma_1, \ldots, \gamma_{qq}) \), \( y = (y_{1111}, \ldots, y_{qqqq}) \) satisfying
\[
\sum_k \gamma_{ik} = \alpha_i \quad (\forall i \in [q]), \\
\sum_i \gamma_{ik} = \alpha_k \quad (\forall k \in [q]), \\
\sum_{j,l} y_{ikjl} = \gamma_{ik} \quad (\forall (i,k) \in [q]^2)
\]
\( \gamma_{ik} \geq 0 \quad (\forall (i,k) \in [q]^2), \quad y_{ikjl} = y_{jilk} \geq 0 \quad (\forall (i,k,j,l) \in [q]^4). \) (262)

The sums in (259) and (261) are typically exponential in \( n \). The most critical component of our arguments is to find the quantitative structure of configurations which determine the exponential order of the moments. Formally, we study the limits of \( \frac{1}{n} \log E_G[Z^\alpha_G] \) and \( \frac{1}{n} \log E_G[(Z^\alpha_G)^2] \) as \( n \to \infty \). These limits are obtainable using Stirling’s approximation. In particular, we shall use that for a constant \( c > 0 \), we have
\[
\frac{1}{n} \log [(cn)!] \sim c \log n + c \log c - c \quad \text{and} \quad \frac{1}{n} \log [(2cn)!]! \sim c \log n + c \log c + c(\log 2 - 1). \quad (263)
\]
Under the usual conventions that \( \ln 0 \equiv -\infty \) and \( 0 \ln 0 \equiv 0 \), the above formulas are correct even in the degenerate case \( c = 0 \).

We now derive asymptotics for the first moment \( E_G[Z^\alpha_G] \) in order to obtain the function \( \Psi_1(\alpha) \). Applying (263) yields:
\[
\Psi_1(\alpha) := \lim_{n \to \infty} \frac{1}{n} \log E_G[Z^\alpha_G] = \max_{X} \Phi_1(\alpha, X), \quad (264)
\]
where \( \Phi_1(\alpha, x) := (\Delta - 1)f_1(\alpha) + \Delta g_1(x) \)
\[
f_1(\alpha) := \sum_i \alpha_i \ln \alpha_i \\
g_1(x) := \frac{1}{2} \sum_{i,j} x_{ij} \ln B_{ij} - \frac{1}{2} \sum_{i,j} x_{ij} \ln x_{ij},
\]
defined on the region (260).

Completely analogously, for the second moment we obtain:
\[
\Psi_2(\gamma) := \lim_{n \to \infty} \frac{1}{n} \log E_G[(Z^\alpha_G)^2] = \max_{y} \max_{\gamma} \Phi_2(\gamma, y), \quad (265)
\]
where \( \Phi_2(\gamma, y) := (\Delta - 1)f_2(\gamma) + \Delta g_2(y) \)
\[
f_2(\gamma) := \sum_{i,k} \gamma_{ik} \ln \gamma_{ik} \\
g_2(y) := \frac{1}{2} \sum_{i,k,j,l} y_{ikjl} \ln (B_{ij}B_{kl}) - \frac{1}{2} \sum_{i,k,j,l} y_{ikjl} \ln y_{ikjl},
\]
Remark 14. As for random bipartite graphs, we can interpret the second moment as the first moment of a paired-spin model with interaction matrix \( B \otimes B \). Indeed, in (265), we can interpret \( B_{ij}B_{kl} \) as the activity between the paired spins \((i,k)\) and \((j,l)\), thus giving the desired alignment.

### 8.5 Small Graph Conditioning Method

In this section, we give the outline for the proof of the following lemma.

**Lemma 101.** For every model \( B \), if \( \alpha \) is dominant and the corresponding fixpoint is Jacobian attractive (c.f. Section 8.3) with probability \( 1 - o(1) \) over the choice of the graph \( G \sim \mathcal{G}_{n,\Delta} \), it holds that \( Z^\alpha_G \geq \frac{1}{n} E[Z^\alpha_G] \).

The proof of Lemma 101 is a minor modification of the arguments in Section 4.2.1 which were carried out for random \( \Delta \)-regular bipartite graphs. Here, we just need to account for the \( \Delta \)-regular case which turns out to be completely analogous. As such, we give only the statements of the necessary lemmas and briefly sketch the proofs.

The main tool we are going to use is the small graph conditioning method, which we described in Section 2.3. For convenience of the reader, we reiterate the statement of the theorem (in a slightly weaker form this time; namely, we do not use the set \( S \) and only the conclusion (C1) is stated).

**Theorem 102.** For \( i = 1, 2, \ldots \), let \( \lambda_i > 0 \) and \( \delta_i > -1 \) be constants and assume that for each \( n \) there are random variables \( X_{in} \), \( i = 1, 2, \ldots \), and \( Y_n \), all defined on the same probability space \( \mathcal{G} = \mathcal{G}_n \) such that \( X_{in} \) is non-negative integer valued, \( Y_n \geq 0 \) and \( E[Y_n] > 0 \) (for \( n \) sufficiently large). Furthermore, the following hold:

(A1) \( X_{in} \xrightarrow{d} Z_i \) as \( n \to \infty \), jointly for all \( i \), where \( Z_i \sim \text{Po}(\lambda_i) \) are independent Poisson random variables;

(A2) for every finite sequence \( j_1, \ldots, j_m \) of non-negative integers,

\[
\frac{E_{\mathcal{G}}[Y_n[X_{1n}]_{j_1} \cdots [X_{mn}]_{j_m}]}{E_{\mathcal{G}}[Y_n]} \to \prod_{i=1}^m (\lambda_i(1 + \delta_i))^{j_i} \quad \text{as } n \to \infty; \quad (266)
\]
(A3) \[ \sum_i \lambda_i \delta_i^2 < \infty; \]

(A4) \[ \mathbb{E}_G \left[ Y_n^2 \right] / (\mathbb{E}_G[|Y_n|]^2 \leq \exp \left( \sum_i \lambda_i \delta_i^2 \right) + o(1) \text{ as } n \to \infty; \]

Let \( r(n) \) be a function such that \( r(n) \to 0 \) as \( n \to \infty \). It holds that \( Y_n > r(n) \mathbb{E}_G[Y_n] \) asymptotically almost surely.

To obtain Lemma 101, it should be clear that it suffices to verify the conditions of Theorem 102 for the random variables \( Z^\alpha_G \). Recall, we restrict our attention to \( \alpha \) which are Hessian dominant. For \( G \sim G(n, \Delta) \), let \( X_i = X_{in} \) be the number of cycles of length \( i \) in \( G \), \( i = 1, 2, \ldots \).

The most technical part of this verification is assumption (A4) which requires computing the precise asymptotics of the moments. This in turn reduces to certain determinants which are not completely trivial. Nevertheless, the arguments have been carried out in full generality in Sections 4.3 and 4.4. The only minor modification required in the present case is to account for the random \( \Delta \)-regular graph setting instead of the bipartite random \( \Delta \)-regular graph setting studied in Sections 4.3 and 4.4.

We obtain the following lemmas.

**Lemma 103.** Assumption (A1) holds with \( \lambda_i = (\Delta - 1)^i / 2i \).

**Lemma 104.** Assumption (A2) holds with \( \delta_i = \sum_{j=1}^{q-1} \mu_j^i \), where \( \mu_1, \mu_2, \ldots, \mu_{q-1} \) are the eigenvalues different than 1 of the matrix

\[ M = \left\{ \frac{B_{ij} R_i R_j}{\alpha_i \alpha_j} \right\}_{i,j=1}^q. \]

For Hessian dominant \( \alpha \), it holds that the \( \mu_i \) are positive and strictly smaller than \( 1 / (\Delta - 1) \).

**Lemma 105.** Assumption (A3) holds with

\[ \sum_i \lambda_i \delta_i^2 = \prod_{i=1}^{q-1} \prod_{j=1}^{q-1} \left( 1 - (\Delta - 1) \mu_i \mu_j \right)^{-1/2}, \]

where the \( \mu_i \)'s are as in Lemma 104.

**Lemma 106.** Assumption (A4) holds.

**Proof of Lemma 101.** Apply Lemmas 103–106 to obtain that the assumptions of Theorem 102 hold. The lemma follows by the conclusion of the theorem, for \( r(n) = 1/n \). \[ \square \]
